Abstract

The DAKOTA (Design Analysis Kit for Optimization and Terascale Applications) toolkit provides a flexible and extensible interface between simulation codes and iterative analysis methods. DAKOTA contains algorithms for optimization with gradient and nongradient-based methods; uncertainty quantification with sampling, analytic reliability, and stochastic finite element methods; parameter estimation with nonlinear least squares methods; and sensitivity analysis with design of experiments and parameter study methods. These capabilities may be used on their own or as components within advanced strategies such as surrogate-based optimization, mixed integer nonlinear programming, or optimization under uncertainty. By employing object-oriented design to implement abstractions of the key components required for iterative systems analyses, the DAKOTA toolkit provides a flexible and extensible problem-solving environment for design and performance analysis of computational models on high performance computers.

This report serves as a reference manual for the commands specification for the DAKOTA software, providing input overviews, option descriptions, and example specifications.

DAKOTA Reference Manual

Author:
Michael S. Eldred, Anthony A. Giunta, Bart G. van Bloemen Waanders, Steven F. Wojtkiewicz, Jr., William E. Hart, Mario P. Alleva

1.1 Introduction

The DAKOTA (Design Analysis Kit for Optimization and Terascale Applications) toolkit provides a flexible, extensible interface between analysis codes and iteration methods. DAKOTA contains algorithms for optimization with gradient and nongradient-based methods, uncertainty quantification with sampling, analytic reliability, and stochastic finite element methods, parameter estimation with nonlinear least squares methods, and sensitivity/primary effects analysis with design of experiments and parameter study capabilities. These capabilities may be used on their own or as components within advanced strategies for surrogate-based optimization, mixed integer nonlinear programming, or optimization under uncertainty. By employing object-oriented design to implement abstractions of the key components required for iterative systems analyses, the DAKOTA toolkit provides a flexible and extensible problem-solving environment as well as a platform for rapid prototyping of advanced solution methodologies.

The Reference Manual focuses on documentation of the various input commands for the DAKOTA system. It follows closely the structure of dakota.input.spec, the master input specification. For information on software structure, refer to the Developers Manual, and for a tour of DAKOTA features and capabilities, refer to the Users Manual [Eldred et al., 2001].

1.2 Input Specification Reference

In the DAKOTA system, the strategy creates and manages iterators and models. A model contains a set of variables, an interface, and a set of responses, and the iterator operates on the model to map the variables into responses using the interface. In a DAKOTA input file, the user specifies these components through strategy, method, variables, interface, and responses keyword specifications. The input specification reference closely follows this structure, with introductory material followed by detailed documentation of the strategy, method, variables, interface, and responses keyword specifications:

DAKOTA File Documentation

2.1 dakota.input.spec File Reference

file containing the input specification for DAKOTA.

2.1.1 Detailed Description

file containing the input specification for DAKOTA.

This file is used in the generation of parser system files which are compiled into the DAKOTA executable. Therefore, this file is the definitive source for input syntax, capability options, and associated data inputs. Refer to Instructions for Modifying DAKOTA's Input Specification for information on how to modify the input specification and propagate the changes through the parsing system.

Key features of the input specification and the associated user input files include:

- In the input specification, required parameters are enclosed in {}, optional parameters are enclosed in [], required groups are enclosed in (), optional groups are enclosed in [ ], and either-or relationships are denoted by the | symbol. These symbols only appear in dakota.input.spec; they must not appear in actual user input files.

- Keyword specifications (i.e., strategy, method, variables, interface, and responses) are delimited by newline characters, both in the input specification and in user input files. Therefore, to continue a keyword specification onto multiple lines, the back-slash character ("\") is needed at the end of a line in order to escape the newline. Continuation onto multiple lines is not required; however, it is commonly used to enhance readability.

- Each of the five keywords in the input specification begins with a
  
  <KEYWORD = name>, <FUNCTION = handler_name>

  header which names the keyword and provides the binding to the keyword handler within DAKOTA's problem description database. In a user input file, only the name of the keyword appears (e.g., variables).
Some of the keyword components within the input specification indicate that the user must supply `INTEGER`, `REAL`, `STRING`, `LISTof` `INTEGER`, `LISTof` `REAL`, or `LISTof` `STRING` data as part of the specification. In a user input file, the "=" is optional, the `<LISTof>` data can be separated by commas or whitespace, and the `<STRING>` data are enclosed in single quotes (e.g., 'text book').

In user input files, input is order-independent (except for entries in data lists) and white-space insensitive. Although the order of input shown in the Sample dakota.in Files generally follows the order of options in the input specification, this is not required.

In user input files, specifications may be abbreviated so long as the abbreviation is unique. For example, the application specification within the interface keyword could be abbreviated as applic, but should not be abbreviated as app since this would be ambiguous with approximation.

In both the input specification and user input files, comments are preceded by `#`.

The `dakota.input.spec` file used in DAKOTA V3.0 is:

```plaintext
# DO NOT CHANGE THIS FILE UNLESS YOU UNDERSTAND THE COMPLETE UPDATE PROCESS
#
# Any changes made to the input specification require the manual merging
# of code fragments generated by IDR into the DAKOTA code. If this manual
# merging is not performed, then libidr.a and the Dakota src files
# (ProblemDescDB.C, keywordtable.C) will be out of sync which will cause
# errors that are difficult to track. Please be sure to consult the
# documentation in Dakota/docs/SpecChange.do x before you modify the input
# specification or otherwise change the IDR subsystem.
#

Chapter 3

Commands Introduction

3.1 Overview

In the DAKOTA system, a strategy governs how each method maps variables into responses through the use of an interface. Each of these five pieces (strategy, method, variables, responses, and interface) are separate specifications in the user’s input file, and as a whole, determine the study to be performed during an execution of the DAKOTA software. The number of strategies which can be invoked during a DAKOTA execution is limited to one. This strategy, however, may invoke multiple methods. Furthermore, each method may (in general) have its own “model,” consisting of its own set of variables, its own set of responses, and its own interface. Thus, there may be multiple specifications of the method, variables, responses, and interface sections.

The syntax of DAKOTA specification is governed by the Input Deck Reader (IDR) parsing system [Weatherby et al., 1996], which uses the dakota.input.spec file to describe the allowable inputs to the system. This input specification file provides a template of the allowable system inputs from which a particular input file (referred to herein as a dakota.in file) can be derived.

This Reference Manual focuses on providing complete details for the allowable specifications in an input file to the DAKOTA program. Related details on the name and location of the DAKOTA program, command line inputs, and execution syntax are provided in the Users Manual [Eldred et al., 2001].

3.2 IDR Input Specification File

DAKOTA input is governed by the IDR input specification file. This file (dakota.input.spec) is used by a code generator to create parsing system components which are compiled into the DAKOTA executable (refer to Instructions for Modifying DAKOTA's Input Specification for additional information). Therefore, dakota.input.spec is the definitive source for input syntax, capability options, and optional and required capability sub-parameters. Beginning users may find this file more confusing than helpful and, in this case, adaptation of example input files to a particular problem may be a more effective approach. However, advanced users can master all of the various input specification possibilities once the structure of the input specification file is understood.

Refer to dakota.input.spec for a listing of the current version. From this file listing, it can be seen that
the main structure of the variables keyword is that of ten optional group specifications for continuous
design, discrete design, normal uncertain, lognormal uncertain, uniform uncertain, loguniform uncertain,
weibull uncertain, histogram uncertain, continuous state, and discrete state variables. Each of these speci-
fications can either appear or not appear as a group. Next, the interface keyword requires the selection of
either an application OR an approximation interface. The type of application interface must be specified
with either a system OR fork OR xml OR direct required group specification, or the type of approxima-
tion interface must be specified with either a global OR multipoint OR local OR hierarchical required
group specification. Within the responses keyword, the primary structure is the required specification
of the function set (either optimization functions OR least squares functions OR generic response func-
tions), followed by the required specification of the gradients (either none OR numerical OR analytic OR
mixed) and the required specification of the Hessians (either none OR analytic). The strategy specifi-
cation requires either a multi-level OR surrogate-based optimization OR optimization under uncertainty
OR branch and bound OR multi-start OR pareto set OR single method strategy specification. Within the
multilevel group specification, either an uncoupled OR a coupled group specification must be supplied.
Lastly, the method keyword is the most lengthy specification; however, its structure is relatively simple.
The structure is simply that of a set of optional method-independent settings followed by a long list of
possible methods appearing as required group specifications (containing a variety of method-dependent
settings) separated by OR’s. Refer to Strategy Commands, Method Commands, Variables Commands,
Interface Commands, and Responses Commands for detailed information on the keywords and their vari-
ous optional and required specifications. And for additional details on IDR specification logic and rules,
refer to [Weatherby et al., 1996].

3.3 Common Specification Mistakes

Spelling and omission of required parameters are the most common errors. Less obvious errors include:

- Documentation of new capability sometimes lags the use of new capability in executables. When
  parsing errors occur which the documentation cannot explain, reference to the particular input spec-
  ification used in building the executable (which is installed alongside the executable) will often
  resolve the errors.

- Since keywords are terminated with the newline character, care must be taken to avoid following the
  backslash character with any white space since the newline character will not be properly escaped,
  resulting in parsing errors due to the truncation of the keyword specification.

- Care must be taken to include newline escapes when embedding comments within a keyword speci-
  fication. That is, newline characters will signal the end of a keyword specification even if they are
  part of a comment line. For example, the following specification will be truncated because one of
  the embedded comments neglects to escape the newline:

\verbatim
# No error here: newline need not be escaped since comment is not embedded
responses,
# No error here: newline is escaped
  num_objective_functions = 1
# Error here: this comment must escape the newline
  analytic_gradients
  no_hessians
\endverbatim

In most cases, the IDR system provides helpful error messages which will help the user isolate the source
of the parsing problem.
3.4 Sample dakota.in Files

A DAKOTA input file is a collection of the fields allowed in the dakota.input.spec specification file which describe the problem to be solved by the DAKOTA system. Several examples follow.

3.4.1 Sample 1: Optimization

The following sample input file shows single-method optimization of the Textbook Example using DOT’s modified method of feasible directions. A similar file (with helpful notes included as comments) is available in the test directory as Dakota/test/dakota_textbook.in.

```
strategy, 
 single_method
 method, 
   dot_mmfd 
   max_iterations = 50, 
   convergence_tolerance = 1e-4  
   output verbose 
   optimization_type minimize
 variables, 
   continuous_design = 2  
   cdv_initial_point 0.9  1.1 
   cdv_upper_bounds  5.8  2.9 
   cdv_lower_bounds  0.5  -2.9 
   cdv_descriptor 'x1' 'x2'
 interface, 
   application system  
   analysis_driver  'text_book'  
   parameters_file  'text_book.in' 
   results_file  'text_book.out' 
   file_tag 
   file_save
 responses, 
   num_objective_functions = 1 
   num_nonlinear_inequality_constraints = 2 
   analytic_gradients 
   no_hessians
```

3.4.2 Sample 2: Least Squares

The following sample input file shows a nonlinear least squares solution of the Rosenbrock Example using OPT++’s Gauss-Newton method. A similar file (with helpful notes included as comments) is available in the test directory as Dakota/test/dakota_rosenbrock.in.

```
strategy, 
 single_method
 method, 
   optpp_bcg_newton 
   max_iterations = 50, 
```
convergence_tolerance = 1e-4

variables,
  continuous_design = 2
  cdv_initial_point = -1.2 1.0
  cdv_lower_bounds = -2.0 -2.0
  cdv_upper_bounds = 2.0 2.0
  cdv_descriptor = 'x1' 'x2'

interface,
  application system
    analysis_driver = 'rosenbrock_ls'

responses,
  num_least_squares_terms = 2
  analytic_gradients
  no_hessians

3.4.3 Sample 3: Nondeterministic Analysis

The following sample input file shows Latin Hypercube Monte Carlo sampling using the Textbook Example. A similar file is available in the test directory as Dakota/test/dakota/textbook lhs.in.

strategy,
  single_method graphics

method,
  nond_sampling
    samples = 100 seed = 1
    sample_type lhs
    response_thresholds = 3.6e+11 6.0e+04 3.5e+05

variables,
  normal_uncertain = 2
    nuv_means = 248.89, 593.33
    nuv_std_deviations = 12.4, 29.7
    nuv_descriptor = 'TF1n' 'TF2n'
  uniform_uncertain = 2
    uuv_dist_lower_bounds = 199.3, 474.63
    uuv_dist_upper_bounds = 298.5, 712
    uuv_descriptor = 'TF1u' 'TF2u'
  weibull_uncertain = 2
    wuv_alphas = 12.0, 30.0
    wuv_betas = 250.0, 590.0
    wuv_descriptor = 'TF1w' 'TF2w'

interface,
  application system asynch evaluation_concurrency = 5
    analysis_driver = 'text_book'

responses,
  num_response_functions = 3
  no_gradients
  no_hessians
3.4 Sample dakota.in Files

3.4.4 Sample 4: Parameter Study

The following sample input file shows a 1-D vector parameter study using the Textbook Example. A similar file is available in the test directory as `Dakota/test/dakota_pstudy.in`.

```
method,
    vector_parameter_study
    step_vector = 1.1.1
    num_steps = 4

variables,
    continuous_design = 3
    cdv_initial_point 1.0 1.0 1.0

interface,
    application_system = asynchronous
    analysis_driver = 'text_book'

responses,
    num_objective_functions = 1
    num_nonlinear_inequality_constraints = 2
    analytic_gradients
    analytic_hessians
```

3.4.5 Sample 5: Multilevel Hybrid Strategy

The following sample input file shows a multilevel hybrid strategy using three iterators. It employs a genetic algorithm, coordinate pattern search and full Newton gradient-based optimization in succession to solve the Textbook Example. A similar file is available in the test directory as `Dakota/test/dakota_multilevel.in`.

```
strategy,
    graphics
    multi_level_uncoupled
    method_list = 'GA' 'CPS' 'NLP'

method,
    id_method = 'GA'
    model_type = single
    variables_pointer = 'V1'
    interface_pointer = 'I1'
    responses_pointer = 'R1'
    sgopt_pga_real
    population_size = 10
    verbose_output

method,
    id_method = 'CPS'
    model_type = single
    variables_pointer = 'V1'
    interface_pointer = 'I1'
    responses_pointer = 'R1'
    sgopt_pattern_search = stochastic
    verbose_output
    initial_delta = 0.1
    threshold_delta = 1.e-4
    solution_accuracy = 1.e-10
    exploratory_moves = best_first
```
method,
  id_method = 'NLP'
  model_type single
  variables_pointer = 'V1'
  interface_pointer = 'I1'
  responses_pointer = 'R2'
  optpp_newton
  gradient_tolerance = 1.e-12
  convergence_tolerance = 1.e-15

variables,
  id_variables = 'V1'
  continuous_design = 2
  cdv_initial_point 0.6 0.7
  cdv_upper_bounds 5.8 2.9
  cdv_lower_bounds 0.5 -2.9
  cdv_descriptor 'x1' 'x2'

interface,
  id_interface = 'I1'
  application direct,
    analysis_driver = 'text_book'

responses,
  id_responses = 'R1'
  num_objective_functions = 1
  no_gradients
  no_hessians

responses,
  id_responses = 'R2'
  num_objective_functions = 1
  analytic_gradients
  analytic_hessians

Additional example input files, as well as the corresponding output and graphics, are provided in the Getting Started chapter of the Users Manual [Eldred et al., 2001].

3.5 Tabular descriptions

In the following discussions of keyword specifications, tabular formats (Tables 4.1 through 8.6) are used to present a short description of the specification, the keyword used in the specification, the type of data associated with the keyword, the status of the specification (required, optional, required group, or optional group), and the default for an optional specification.

It can be difficult to capture in a simple tabular format the complex relationships that can occur when specifications are nested within multiple groupings. For example, in an interface keyword, the parameters_file specification is an optional specification within the system and fork required group specifications, which are separated from each other and from other required group specifications (xml and direct) by logical OR's. The selection between the system, fork, xml, or direct required groups is contained within another required group specification (application), which is separated from the approximation required group specification by a logical OR. Rather than unnecessarily proliferate the number of tables in attempting to capture all of these inter-relationships, a balance is sought, since some inter-relationships are more easily discussed in the associated text. The general structure of the following sections is to present the outermost specification groups first (e.g., application in Table 7.2), followed by lower levels of specifications (e.g., system, fork, xml, or direct in Tables 7.3 through 7.6) in
succession.
Chapter 4

Strategy Commands

4.1 Strategy Description

The strategy section in a DAKOTA input file specifies the top level technique which will govern the management of iterators and models in the solution of the problem of interest. Seven strategies currently exist: multi_level, surrogate_based_opt, opt_under_uncertainty, branch_and_bound, multi_start, pareto_set, and single_method. These algorithms are implemented within the DakotaStrategy class hierarchy in the MultilevelOptStrategy, SurrBasedOptStrategy, NonDOptStrategy, BranchBndStrategy, ConcurrentStrategy, and SingleMethodStrategy classes. For each of the strategies, a brief algorithm description is given below. Additional information on the algorithm logic is available in the Users Manual.

In a multi-level hybrid optimization strategy (multi_level), a list of methods is specified which will be used synergistically in seeking an optimal design. The goal here is to exploit the strengths of different optimization algorithms through different stages of the optimization process. Global/local hybrids (e.g., genetic algorithms combined with nonlinear programming) are a common example in which the desire for a global optimum is balanced with the need for efficient navigation to a local optimum.

In surrogate-based optimization (surrogate_based_opt), an approximate model is built using data from a "truth" model (e.g., using a set of points from a design of computer experiments). This approximation could be a global data fit, a multipoint approximation, a local series expansion, or a hierarchical approximation. An optimizer iterates on this approximate model and computes an approximate optimum. This point is evaluated with the truth model and the measured improvement in the simulation model is used to either accept or reject the new point and then modify the boundaries (i.e., shrink/expand/translate the trust region) of the approximation. The cycle then repeats with the construction of a new approximation and additional approximate optimization cycles are performed until convergence. The goals with surrogate-based optimization are to reduce the total number of truth model simulations and, in the global approximation case, to smooth noisy data with an easily navigated analytic fit.

In optimization under uncertainty (opt_under_uncertainty), a nondeterministic iterator is used to evaluate the effect of uncertain variables, modeled using probabilistic distributions, on responses of interest. Statistics on these responses are then included in the objective and constraint functions of the optimization problem (for example, to minimize probability of failure). The nondeterministic iterator may be nested directly within the optimization function evaluations, which can be prohibitively expensive, or the direct nesting can be broken through a variety of surrogate-based optimization under uncertainty formulations. The sub-model recursion features of NestedModel, SurrLayeredModel, and HierLayeredModel enable
these formulations.

In the branch and bound strategy (branch\&bound), mixed integer nonlinear programs (nonlinear applications with a mixture of continuous and discrete variables) can be solved through the combination of the PICO parallel branching algorithm with the nonlinear programming algorithms available in DAKOTA. Since PICO supports parallel branch and bound techniques, multiple bounding operations can be performed concurrently for different branches, which provides for concurrency in nonlinear optimizations for DAKOTA. This is an additional level of parallelism, beyond those for concurrent evaluations within an iterator, concurrent analyses within an evaluation, and multiprocessor analyses. Branch and bound is applicable when the discrete variables can assume continuous values during the solution process (i.e., the integrality conditions are relaxable). It proceeds by performing a series of continuous-valued optimizations for different variable bounds which, in the end, drive the discrete variables to integer values.

In the multi-start iteration strategy (multi\_start), a series of iterator runs are performed for different values of some parameters in the model. A common use is for multi-start optimization (i.e., different optimization runs from different starting points for the design variables), but the concept and the code are more general. An important feature is that these iterator runs are performed concurrently, similar to the branch and bound strategy discussed above.

In the pareto set optimization strategy (pareto\_set), a series of optimization runs are performed for different weightings applied to multiple objective functions. This set of optimal solutions defines a "Pareto set", which is useful for investigating design trade-offs between competing objectives. An important feature is that these iterator runs are performed concurrently, similar to the branch and bound and multi-start strategies discussed above. The code is similar enough to the multi\_start technique that both strategies are implemented in the same ConcurrentStrategy class.

Lastly, the single\_method strategy is a "fall through" strategy in that it does not provide control over multiple iterators and models. Rather, it provides the means for simple execution of a single iterator on a single model.

Each of the strategy specifications identifies one or more method pointers (e.g., method\_list, opt\_method\_pointer) to identify the iterators that will be used in the strategy. These method pointers are strings that correspond to the id\_method identifier strings from the method specifications (see Method Independent Controls). These string identifiers (e.g., ‘NLP1’) should not be confused with method selections (e.g., dot\_mmfd). Each of the method specifications identified in this manner has the responsibility for identifying the variables, interface, and responses specifications (using variables\_pointer, interface\_pointer, and responses\_pointer from Method Independent Controls) that are used to build the model used by the iterator. If a method specification does not provide a particular pointer, then that component of the model will be built using the last specification parsed. In addition to method pointers, a variety of graphics options (e.g., tabular\_graphics\_data), iterator concurrency controls (e.g., iterator\_servers), and strategy data (e.g., starting\_points) can be specified.

Specification of a strategy block in an input file is optional, with single\_method being the default strategy. If no strategy is specified or if single\_method is specified without its optional method\_pointer specification, then the default behavior is to employ the last method, variables, interface, and responses specifications parsed. This default behavior is most appropriate if only one specification is present for method, variables, interface, and responses, since there is no source for confusion in this case.

Example specifications for each of the strategies follow. A multi\_level example is:

```
strategy,  
  multi_level uncoupled \  
  method_list = 'GA1', 'CPS1', 'NLP1'
```

A surrogate\_based\_opt example specification is:

```
strategy,  
  graphics \  
```

Generated on Mon Apr 1 12:29:12 2002 for DAKOTA by Doxygen written by Dimitri van Heesch @ 1997-2001
surrogate_based_opt
  \opt_method_pointer = 'NLP1'
trust_region initial_size = 0.10

An \texttt{opt\_under\_uncertainty} example specification is:

\begin{verbatim}
strategy, \opt_under_uncertainty \opt_method = 'NLP1'
\end{verbatim}

A \texttt{branch\_and\_bound} example specification is:

\begin{verbatim}
strategy, \	iterator_servers = 4 \	\branch_and_bound \opt_method = 'NLP1'
\end{verbatim}

A \texttt{multi\_start} example specification is:

\begin{verbatim}
strategy, \	multi_start \method_pointer = 'NLP1' \num_starts = 10
\end{verbatim}

A \texttt{pareto\_set} example specification is:

\begin{verbatim}
strategy, \	pareto_set \opt_method_pointer = 'NLP1' \num_optima = 10
\end{verbatim}

And finally, a \texttt{single\_method} example specification is:

\begin{verbatim}
strategy, \	single_method \method_pointer = 'NLP1'
\end{verbatim}

\section{4.2 Strategy Specification}

The strategy specification has the following structure:

\begin{verbatim}
strategy, \langle strategy independent controls \rangle \langle strategy selection \rangle \langle strategy dependent controls \rangle
\end{verbatim}

where \texttt{\langle strategy selection \rangle} is one of the following:
multi\_level, surrogate\_based\_opt, opt\_under\_uncertainty, branch\_and\_bound, multi\_start, pareto\_set, or single\_method

The \texttt{\langle strategy independent controls \rangle} are those controls which are valid for a variety of strategies. Unlike the \texttt{Method Independent Controls}, which can be abstractions with slightly different implementations from
one method to the next, the implementations of each of the strategy independent controls are consistent for all strategies that use them. The <strategy dependent controls> are those controls which are only meaningful for a specific strategy. Referring to dakota.input.spec, the strategy independent controls are those controls defined externally from and prior to the strategy selection blocks. They are all optional. The strategy selection blocks are all required group specifications separated by logical OR's (multi_level or surrogate_based_opt or opt_under_uncertainty or branch_and_bound or multi_start or pareto_set or single_method). Thus, one and only one strategy selection must be provided. The strategy dependent controls are those controls defined within the strategy selection blocks. The following sections provide additional detail on the strategy independent controls followed by the strategy selections and their corresponding strategy dependent controls.

4.3 Strategy Independent Controls

The strategy independent controls include graphics, tabular_graphics_data, tabular_graphics_file, iterator_servers, iterator_self_scheduling, and iterator_static_scheduling. The graphics flag activates a 2D graphics window containing history plots for the variables and response functions in the study. This window is updated in an event loop with approximately a 2 second cycle time. For applications utilizing approximations over 2 variables, a 3D graphics window containing a surface plot of the approximation will also be activated. The tabular_graphics_data flag activates file tabulation of the same variables and response function history data that gets passed to graphics windows with use of the graphics flag. The tabular_graphics_file specification optionally specifies a name to use for this file (dakota_tabular.dat is the default). Within the file, the variables and response functions appear as columns and each function evaluation provides a new table row. This capability is most useful for post-processing of DAKOTA results with 3rd party graphics tools such as MATLAB or Tecplot. There is no dependence between the graphics flag and the tabular_graphics_data flag: they may be used independently or concurrently. The iterator_servers, iterator_self_scheduling, and iterator_static_scheduling specifications provide manual overrides for the number of concurrent iterator partitions and the scheduling policy for concurrent iterator jobs. These settings are normally determined automatically in the parallel configuration routines (see ParallelLibrary) but can be overridden with user inputs if desired. The graphics, tabular_graphics_data, and tabular_graphics_file specifications are valid for all strategies. However, the iterator_servers, iterator_self_scheduling, and iterator_static_scheduling overrides are only useful inputs for those strategies supporting concurrency in iterators, i.e. branch_and_bound, multi_start, and pareto_set (opt_under_uncertainty will support this in the future once full NestedModel parallelism support is in place). Table 4.1 summarizes the strategy independent controls.

Table 4.1 Specification detail for strategy independent controls
### 4.4 Multilevel Hybrid Optimization Commands

The multi-level hybrid optimization strategy has uncoupled, uncoupled adaptive, and coupled approaches (see the Users Manual for more information on the algorithms employed). In the two uncoupled approaches, a list of method strings supplied with the `method_list` specification specifies the identity and sequence of iterators to be used. Any number of iterators may be specified. The uncoupled adaptive approach may be specified by turning on the `adaptive` flag. If this flag is specified, then `progress_threshold` must also be specified since it is a required part of the optional group specification. In the nonadaptive case, method switching is managed through the separate convergence controls of each method. In the adaptive case, however, method switching occurs when the internal progress metric (normalized between 0.0 and 1.0) falls below the user specified `progress_threshold`. Table 4.2 summarizes the uncoupled multi-level strategy inputs.

#### Table 4.2 Specification detail for uncoupled multi-level strategies

In the coupled approach, global and local method strings supplied with the `global_method_pointer` and `local_method_pointer` specifications identify the two methods to be used. The `local_search_probability` setting is an optional specification for supplying the probability (between 0.0 and 1.0) of employing local search to improve estimates within the global search. Table 4.3 summarizes the coupled multi-level strategy inputs.

### 4.5 Surrogate-based Optimization Commands

The surrogate-based_opt strategy must specify an optimization method using `opt.method_pointer`. The method specification identified by `opt.method_pointer` is responsible for selecting a layered model for use as the surrogate (see Method Independent Controls). In addition, the `trust.region` optional group specification can be used to specify the initial size of the trust region (using `initial.size`), the contraction factor for the trust region (using `contraction.factor`) used when the approximation is performing poorly, and the expansion factor for the trust region (using `expansion.factor`) used when the approximation is performing well. Table 4.4 summarizes the surrogate based optimization strategy inputs.

4.6 Optimization Under Uncertainty Commands

The `opt_under_uncertainty` strategy must specify an optimization iterator using `opt_method_pointer`. In the case of a direct nesting of an uncertainty quantification iterator within the top level model, the method specification identified by `opt_method_pointer` would select a nested model (see Method Independent Controls). In the case of surrogate-based optimization under uncertainty, the method specification identified by `opt_method_pointer` might select either a nested model or a layered model, since the recursive properties of NestedModel, SurrLayeredModel, and HierLayeredModel could be utilized to configure any of the following:

- "layered containing nested" (i.e., optimization of a data fit surrogate built using statistical data from nondeterministic analyses)
- "nested containing layered" (i.e., optimization using nondeterministic analysis data evaluated from a data fit or hierarchical surrogate)
- "layered containing nested containing layered" (i.e., combination of the two above: optimization of a data fit surrogate built using statistical data from nondeterministic analyses, where the nondeterministic analyses are performed on a data fit or hierarchical surrogate)

Since most of the sophistication is encapsulated within the nested and layered model classes, the optimization under uncertainty strategy inputs are minimal. Table 4.5 summarizes these inputs.

Table 4.5 Specification detail for optimization under uncertainty strategies

4.7 Branch and Bound Commands

The `branch_and_bound` strategy must specify an optimization method using `opt_method_pointer`. This optimization method is responsible for computing optimal solutions to nonlinear programs which arise from different branches of the mixed variable problem. These branches correspond to different bounds on the discrete variables where the integrality constraints on these variables have been relaxed. Solutions which are completely feasible with respect to the integrality constraints provide an upper bound on the final solution and can be used to prune branches which are not yet completely feasible and which have higher objective functions. The optional `num_samples_at_root` and `num_samples_at_node` specifications specify the number of additional function evaluations to perform at the root of the branching structure and at each node of the branching structure, respectively. These samples are selected randomly within the current variable bounds of the branch. This feature is a simple way to globalize the optimization of the branches, since nonlinear problems may be multimodal. Table 4.6 summarizes the branch and bound strategy inputs.

Table 4.6 Specification detail for branch and bound strategies
4.8 Multistart Iteration Commands

The multistart strategy must specify an iterator using method_pointer. This iterator is responsible for completing a series of iterative analyses from a user specified set of different starting points. These starting points are specified using either num_starts, in which case starting values are selected randomly within the bounds, or starting_points, in which the starting values are provided in a list. The most common example of a multi-start strategy is multi-start optimization, in which a series of optimizations are performed from different starting values for the design variables. This can be an effective approach for problems with multiple minima. Table 4.7 summarizes the multi-start strategy inputs.

4.9 Pareto Set Optimization Commands

The pareto set strategy must specify an optimization method using opt_method_pointer. This optimizer is responsible for computing a set of optimal solutions for a user specified set of multiobjective weightings. These weightings are specified using either num_optima, in which case weightings are selected randomly within [0,1] bounds, or multi_objective_weight_sets, in which the weighting sets are provided in a list. The set of optimal solutions is called a "pareto set," which can provide valuable design trade-off information when there are competing objectives. Table 4.8 summarizes the pareto set strategy inputs.

4.10 Single Method Commands

The single method strategy is the default if no strategy specification is included in a user input file. It may also be specified using the single_method keyword within a strategy specification. An optional method_pointer specification may be used to point to a particular method specification. If method_pointer is not used, then the last method specification parsed will be used as the iterator. Table 4.9 summarizes the single method strategy inputs.

Chapter 5

Method Commands

5.1 Method Description

The method section in a DAKOTA input file specifies the name and controls of an iterator. The terms "method" and "iterator" can be used interchangeably, although method usually refers to an input specification whereas iterator usually refers to an object within the DakotaIterator hierarchy. A method specification, then, is used to select an iterator from the iterator hierarchy (see DakotaIterator), which includes optimization, uncertainty quantification, least squares, design of experiments, and parameter study iterators (see Users Manual for more information on these iterator branches). This iterator may be used alone or in combination with other iterators as dictated by the strategy specification (refer to Strategy Commands for strategy command syntax and to the Users Manual for strategy algorithm descriptions).

Several examples follow. The first example shows a minimal specification for an optimization method.

```plaintext
method, dot_sqp
```

This example uses all of the method defaults.

A more sophisticated example would be

```plaintext
method, id_method = 'NLPI'
    model_type single
    variables_pointer = 'V1'
    interface_pointer = 'I1'
    responses_pointer = 'R1'
    dot_sqp
    max_iterations = 50
    convergence_tolerance = 1e-4
    output verbose
    optimization_type minimize
```

This example demonstrates the use of identifiers and pointers (see Method Independent Controls) as well as some method independent and method dependent controls for the sequential quadratic programming (SQP) algorithm from the DOT library. The max_iterations, convergence_tolerance,
and output settings are method independent controls, in that they are defined for a variety of methods (see DOT method independent controls for DOT usage of these controls). The optimization_type control is a method dependent control, in that it is only meaningful for DOT methods (see DOT method dependent controls).

The next example shows a specification for a least squares method.

```plaintext
method, 
  optpp_g_newton 
  max_iterations = 10 
  convergence_tolerance = 1.e-8 
  search_method trust_region 
  gradient_tolerance = 1.e-6
```

Some of the same method independent controls are present along with a new set of method dependent controls (search_method and gradient_tolerance) which are only meaningful for OPT++ methods (see OPT++ method dependent controls).

The next example shows a specification for a nondeterministic iterator with several method dependent controls (refer to Nondeterministic sampling method).

```plaintext
method, 
  nond_sampling 
  samples = 100 seed = 1 
  sample_type lhs 
  response_thresholds = 1000. 500.
```

The last example shows a specification for a parameter study iterator where, again, each of the controls are method dependent (refer to Vector parameter study).

```plaintext
method, 
  vector_parameter_study 
  step_vector = 1. 1. 1. 
  num_steps = 10
```

### 5.2 Method Specification

As alluded to already in the examples above, the method specification has the following structure:

```plaintext
method, 
  <method independent controls>
  <method selection>
  <method dependent controls>
```

where `<method selection>` is one of the following: dot_frcg, dot_mmfd, dot_bfgs, dot_slp, dot_sqp, npsol_sqp, conmin_frcg, conmin_mfd, optpp_cg, optpp_q_newton, optpp_s_newton, optpp_f_newton, optpp_baq Newton, optpp_ba Newton, optpp_bcq Newton, optpp_bc Newton, optpp_bc_ellipsoid, optpp_nips, optpp_qnips, optpp_fd_nips, optpp_pds, apps, sgopt_pga_real, sgopt_pga_int, sgopt_psa, sgopt_pattern_search, sgopt_solis_wets, sgopt_strat_mc, nond_polynomial_chaos, nond_sampling, nond_analytic_reliability, dace, vector_parameter_study, list_parameter_study, centered_parameter_study, or multidim_parameter_study.
5.3 Method Independent Controls

The <method independent controls> are those controls which are valid for a variety of methods. In some cases, these controls are abstractions which may have slightly different implementations from one method to the next. The <method dependent controls> are those controls which are only meaningful for a specific method or library. Referring to dakota.input.spec, the method independent controls are those controls defined externally from and prior to the method selection blocks. They are all optional. The method selection blocks are all required group specifications separated by logical OR’s. The method dependent controls are those controls defined within the method selection blocks. Defaults for method independent and method dependent controls are defined in DataMethod. The following sections provide additional detail on the method independent controls followed by the method selections and their corresponding method dependent controls.

5.3 Method Independent Controls

The method independent controls include a method identifier string, a model type specification with pointers to variables, interface, and responses specifications, a speculative gradient selection, an output verbosity control, maximum iteration and function evaluation limits, constraint and convergence tolerance specifications, and a set of linear inequality and equality constraint specifications. While each of these controls is not valid for every method, the controls are valid for enough methods that it was reasonable to pull them out of the method dependent blocks and consolidate the specifications.

The method identifier string is supplied with id.method and is used to provide a unique identifier string for use with strategy specifications (see Strategy Description). It is appropriate to omit a method identifier string if only one method is included in the input file and single.method is the selected strategy (all other strategies require one or more method pointers), since the single method to use is unambiguous in this case.

The type of model to be used by the method is supplied with model.type and can be single, nested, or layered (refer to Dakotamodel for the class hierarchy involved). In the single model case, the optional variables pointer, interface pointer, and responses pointer specifications provide strings for cross-referencing with id.variables, id.interface, and id.responses string inputs from particular variables, interface, and responses keyword specifications. These pointers identify which specifications will be used in building the single model, which is to be iterated by the method to map the variables into responses through the interface. In the layered model case, the specification is similar, except that the interface.pointer specification is required in order to identify a global, multipoint, local, or hierarchical approximation interface (see Approximation Interface) to use in the layered model. In the nested model case, a sub.method pointer must be provided in order to specify the nested iterator, and interfacepointer and interface.responses pointer provide an optional group specification for the optional interface portion of nested models (where interfacepointer points to the interface specification and interface.responses pointer points to a responses specification describing the data to be returned by this interface). This interface is used to provide non-nested data, which is then combined with data from the nested iterator using the primary.mapping matrix and secondary.mapping.matrix inputs (refer to NestedModel::response_mapping() for additional information). In all cases, if a pointer string is specified and no corresponding id is available, DAKOTA will exit with an error message. If no pointer string is specified, the last specification parsed will be used. It is appropriate to omit this cross-referencing whenever the relationships are unambiguous due to the presence of only one specification. Since the method specification is responsible for cross-referencing with the interface, variables, and responses specifications, identification of methods at the strategy layer is often sufficient to completely specify all of the object interrelationships.

Table 5.1 provides the specification detail for the method independent controls involving identifiers, pointers, and model type controls.

When performing gradient-based optimization in parallel, speculative gradients can be selected to address the load imbalance that can occur between gradient evaluation and line search phases. In a typical synchronous analysis, the line search phase consists primarily of evaluating the objective function and any constraints at a trial point, and then testing the trial point for a sufficient decrease in the objective function value and/or constraint violation. If a sufficient decrease is not observed, then one or more additional trial points may be attempted in series. However, if the trial point is accepted then the line search phase is complete and the gradient evaluation phase begins. By speculating that the gradient information associated with a given line search trial point will be used later, additional coarse grained parallelism can be introduced during an asynchronous analysis. This is achieved by computing the gradient information, either by finite difference or analytically, in parallel, at the same time as the line search phase trial-point function values. This balances the total amount of computation to be performed at each design point and allows for efficient utilization of multiple processors. While the total amount of work performed will generally increase (since some speculative gradients will not be used when a trial point is rejected in the line search phase), the run time will usually decrease (since gradient evaluations needed at the start of each new optimization cycle...
5.3 Method Independent Controls

were already performed in parallel during the line search phase). Refer to [Byrd et al., 1998] for additional details. The speculative specification is implemented for the gradient-based optimizers in the DOT, NPSOL, and OPT++ libraries, and it can be used with dakota numerical or analytic gradient selections in the responses specification (refer to Gradient Specification for information on these specifications). It should not be selected with vendor numerical gradients since vendor internal finite difference algorithms have not been modified for this purpose. In full-Newton approaches, the Hessian is also computed speculatively.

Output verbosity control is specified with output followed by quiet, verbose, or debug. This control is mapped into each iterator as well as components of the model to manage the volume of data that is returned to the user during the course of the iteration. Output verbosity is observed within DakotaIterator, DakotaInterface (scheduler verbosity), and AnalysisCode (file operations verbosity) with the following meanings:

- "quiet": quiet iterators, quiet interface, quiet file operations
- "normal": quiet iterators, verbose interface, quiet file operations
- "verbose": verbose iterators, debug interface, verbose file operations
- "debug": debug iterators, debug interface, verbose file operations

where "quiet", "verbose", and "debug" must be user specified and "normal" is the default for no user specification. With respect to iterator verbosity, different iterators implement this control in slightly different ways, however the meaning is consistent.

The constraint tolerance specification determines the maximum allowable value of infeasibility that any constraint in an optimization problem may possess and still be considered to be satisfied. It is specified as a positive real value. If a constraint function is greater than this value then it is considered to be violated by the optimization algorithm. This specification gives some control over how tightly the constraints will be satisfied at convergence of the algorithm. However, if the value is set too small the algorithm may terminate with one or more constraints being violated. This specification is currently meaningful for the NPSOL and DOT constrained optimizers (refer to DOT method independent controls and NPSOL method independent controls).

The convergence tolerance specification provides a real value for controlling the termination of iteration. In most cases, it is a relative convergence tolerance for the objective function; i.e., if the change in the objective function between successive iterations divided by the previous objective function is less than the amount specified by convergence tolerance, then this convergence criterion is satisfied on the current iteration. Since no progress may be made on one iteration followed by significant progress on a subsequent iteration, some libraries require that the convergence tolerance be satisfied on two or more consecutive iterations prior to termination of iteration. This control is used with optimization and least squares iterators and is not used within the uncertainty quantification, design of experiments, or parameter study iterator branches. Refer to the DOT, NPSOL, OPT++, and SGOPT specifications for the specific interpretation of convergence tolerance for these libraries (see DOT method independent controls, NPSOL method independent controls, OPT++ method independent controls, and SGOPT method independent controls).

The max iterations and max function evaluations controls provide integer limits for the maximum number of iterations and maximum number of function evaluations, respectively. The difference between an iteration and a function evaluation is that a function evaluation involves a single parameter to response mapping through an interface, whereas an iteration involves a complete cycle of computation within the iterator. Thus, an iteration generally involves multiple function evaluations (e.g., an iteration contains descent direction and line search computations in gradient-based optimization, population and multiple offset evaluations in nongradient-based optimization, etc.). This control is not currently used within the uncertainty quantification, design of experiments, and parameter study iterator branches, and in the case of optimization and least squares, does not currently capture function evaluations that occur as part of the method source dakota finite difference routine (since these additional evaluations are intentionally isolated from the iterators).
Table 5.2 provides the specification detail for the method independent controls involving tolerances, limits, output verbosity, and speculative gradients.

Linear inequality constraints can be supplied with the `linear_inequality_constraint_matrix`, `linear_inequality_lower_bounds`, and `linear_inequality_upper_bounds` specifications, and linear equality constraints can be supplied with the `linear_equality_constraint_matrix` and `linear_equality_targets` specifications. In the inequality case, the constraint matrix provides coefficients for the variables, and the lower and upper bounds provide constraint limits for the following two-sided formulation:

\[ a_l \leq Ax \leq a_u \]

As with nonlinear inequality constraints (see Objective and constraint functions (optimization data set)), the default linear inequality constraint bounds are selected so that one-sided inequalities of the form

\[ Ax \leq 0.0 \]

result when there are no user bounds specifications (this provides backwards compatibility with previous DAKOTA versions). In a user bounds specification, any upper bound values greater than +bigBoundSize (1.e+30, as defined in DakotaOptimizer) are treated as +infinity and any lower bound values less than -bigBoundSize are treated as -infinity. This feature is commonly used to drop one of the bounds in order to specify a 1-sided constraint (just as the default lower bounds drop out since -DBL_MAX < -bigBoundSize). The same approach is used for the nonlinear inequality bounds as described in Objective and constraint functions (optimization data set). In the equality case, the constraint matrix again provides coefficients for the variables, and the targets provide the equality constraint right hand sides:

\[ Ax = a_t \]

and the defaults for the equality constraint targets enforce a value of 0.0 for each constraint

\[ Ax = 0.0 \]

Currently, DOT, NPSOL, CONMIN, and OPT++ all support specialized handling of linear constraints. SGOPT optimizers will support linear constraints in future releases. Linear constraints need not be computed by the user’s interface on every function evaluation; rather the coefficients, bounds, and targets of the linear constraints can be provided at start up, allowing the optimizers to track the linear constraints.
internally. It is important to recognize that linear constraints are those constraints that are linear in the design variables, e.g.:

\[
0.0 \leq 3x_1 - 4x_2 + 2x_3 \leq 15.0 \\
x_1 + x_2 + x_3 \geq 2.0 \\
x_1 + x_2 - x_3 = 1.0
\]

which is not to be confused with something like

\[
s(X) - s_{\text{fail}} \leq 0.0
\]

which is linear in a response quantity, but the response quantity is a nonlinear implicit function of the design variables. For the three linear constraints above, the specification would appear as:

```plaintext
linear_inequality_constraint_matrix = 3.0 -4.0 2.0 \\
                                   1.0 1.0 1.0 \\
linear_inequality_lower_bounds = 0.0 2.0 \\
linear_inequality_upper_bounds = 15.0 1.e+50 \\
linear_equation_constraint_matrix = 1.0 1.0 -1.0 \\
linear_equation_targets = 1.0
```

where the 1.e+50 is a dummy upper bound value which defines a 1-sided inequality since it is greater than bigBoundSize. The constraint matrix specifications list the coefficients of the first constraint followed by the coefficients of the second constraint, and so on. They are divided into individual constraints based on the number of design variables, and can be broken onto multiple lines for readability as shown above.

Table 5.3 provides the specification detail for the method independent controls involving linear constraints.

5.4 DOT Methods

The DOT library [Vanderplaats Research and Development, 1995] contains nonlinear programming optimizers, specifically the Broyden-Fletcher-Goldfarb-Shanno (DAKOTA’s dot_bfgs method) and Fletcher-Reeves conjugate gradient (DAKOTA’s dot_frcg method) methods for unconstrained optimization,
and the modified method of feasible directions (DAKOTA's dot-mmfd method), sequential linear programming (DAKOTA's dot-slp method), and sequential quadratic programming (DAKOTA's dot-sqp method) methods for constrained optimization. DAKOTA provides access to the DOT library through the DOTOptimizer class.

5.4.1 DOT method independent controls

The method independent controls for max iterations and max function evaluations limit the number of major iterations and the number of function evaluations that can be performed during a DOT optimization. The convergence tolerance control defines the threshold value on relative change in the objective function that indicates convergence. This convergence criterion must be satisfied for two consecutive iterations before DOT will terminate. The constraint tolerance specification defines how tightly constraint functions are to be satisfied at convergence. The default value for DOT constrained optimizers is 0.003. Extremely small values for constraint tolerance may not be attainable. The output verbosity specification controls the amount of information generated by DOT; the quiet setting results in header information, final results, and objective function, constraint, and parameter information on each iteration; whereas the verbose or debug setting adds additional information on gradients, search direction, one-dimensional search results, and parameter scaling factors. DOT contains no parallel algorithms which can directly take advantage of asynchronous evaluations. However, if numerical gradients with method source dakota is specified, then the finite difference function evaluations can be performed concurrently (using any of the parallel modes described in the Users Manual). In addition, if speculative is specified, then gradients (dakota numerical or analytic gradients) will be computed on each line search evaluation in order to balance the load and lower the total run time in parallel optimization studies. Lastly, specialized handling of linear constraints is supported with DOT; linear constraint coefficients, bounds, and targets can be provided to DOT at start-up and tracked internally. Specification detail for these method independent controls is provided in Tables 5.1 through 5.3.

5.4.2 DOT method dependent controls

DOT’s only method dependent control is optimization type which may be either minimize or maximize. DOT has the only methods within DAKOTA which provide this control; to convert a maximization problem into the minimization formulation assumed by other methods, simply change the sign on the objective function (i.e., multiply by -1). Table 5.4 provides the specification detail for the DOT methods and their method dependent controls.

5.5 NPSOL Method

The NPSOL library [Gill et al., 1986] contains a sequential quadratic programming (SQP) implementation (the npsol-sqp method). SQP is a nonlinear programming optimizer for constrained minimization. DAKOTA provides access to the NPSOL library through the NPSOLOptimizer class.
5.5 NPSOL Method

5.5.1 NPSOL method independent controls

The method independent controls for max_iterations and max_function_evaluations limit the number of major SQP iterations and the number of function evaluations that can be performed during an NPSOL optimization. The convergence_tolerance control defines NPSOL's internal optimality tolerance which is used in evaluating if an iterate satisfies the first-order Kuhn-Tucker conditions for a minimum. The magnitude of convergence_tolerance approximately specifies the number of significant digits of accuracy desired in the final objective function (e.g., convergence_tolerance = 1.e-6 will result in approximately six digits of accuracy in the final objective function). The constraint_tolerance control defines how tightly the constraint functions are satisfied at convergence. The default value is dependent upon the machine precision of the platform in use, but is typically on the order of 1.e-8 for double precision computations. Extremely small values for constraint_tolerance may not be attainable. The output verbosity setting controls the amount of information generated at each major SQP iteration: the quiet setting results in only one line of diagnostic output for each major iteration and prints the final optimization solution, whereas the verbose or debug setting adds additional information on the objective function, constraints, and variables at each major iteration.

NPSOL is not a parallel algorithm and cannot directly take advantage of asynchronous evaluations. However, if numerical_gradients with method_source dakota is specified, then the finite difference function evaluations can be performed concurrently (using any of the parallel modes described in the Users Manual). An important related observation is the fact that NPSOL uses two different line searches depending on how gradients are computed. For either analytic_gradients or numerical_gradients with method_source dakota, NPSOL is placed in user-supplied gradient mode (NPSOL's "Derivative Level" is set to 3) and it uses a gradient-based line search (presumably since it assumes that the user-supplied gradients are inexpensive). On the other hand, if numerical_gradients are selected with method_source vendor, then NPSOL is computing finite differences internally and it will use a value-based line search (presumably since it assumes that finite differencing on each line search evaluation is too expensive). The ramifications of this are: (1) performance will vary between method_source dakota and method_source vendor for numerical_gradients, and (2) gradient speculation is unnecessary when performing optimization in parallel since the gradient-based line search in user-supplied gradient mode is already load balanced for multiple processor execution. Therefore, a speculative specification will be ignored by NPSOL, and optimization with numerical gradients should select method_source dakota for load balanced parallel operation and method_source vendor for efficient serial operation.

Lastly, NPSOL supports specialized handling of linear inequality and equality constraints. By specifying the coefficients and bounds of the linear inequality constraints and the coefficients and targets of the linear equality constraints, this information can be provided to NPSOL at initialization and tracked internally, removing the need for the user to provide the values of the linear constraints on every function evaluation. Refer to Method Independent Controls for additional information and to Tables 5.1 through 5.3 for method independent control specification detail.

5.5.2 NPSOL method dependent controls

NPSOL’s method dependent controls are verify_level, function_precision, and linesearch_tolerance. The verify_level control instructs NPSOL to perform finite difference verifications on user-supplied gradient components. The function_precision control provides NPSOL an estimate of the accuracy to which the problem functions can be computed. This is used to prevent NPSOL from trying to distinguish between function values that differ by less than the inherent error in the calculation. And the linesearch_tolerance setting controls the accuracy of the line search. The smaller the value (between 0 and 1), the more accurately NPSOL will attempt to compute a precise minimum along the search direction. Table 5.5 provides the specification detail for the NPSOL SQP method and its method
dependent controls.

5.6 CONMIN Methods

The CONMIN library [Vanderplaats, 1973] is a public domain library of nonlinear programming optimizers, specifically the Fletcher-Reeves conjugate gradient (DAKOTA’s conmin.frcg method) method for unconstrained optimization, and the method of feasible directions (DAKOTA’s conmin.fmd method) for constrained optimization. As CONMIN was a predecessor to the DOT commercial library, the algorithm controls are very similar. DAKOTA provides access to the CONMIN library through the CONMINOptimizer class.

5.6.1 CONMIN method independent controls

The interpretations of the method independent controls for CONMIN are essentially identical to those for DOT. Therefore, the discussion in DOT method independent controls is relevant for CONMIN.

5.6.2 CONMIN method dependent controls

CONMIN does not currently support any method dependent controls.

5.7 OPT++ Methods

The OPT++ library [Meza, 1994] contains primarily nonlinear programming optimizers for unconstrained, bound-constrained, and nonlinearly constrained minimization: Polak-Ribiere conjugate gradient (DAKOTA’s optpp.cg method), quasi-Newton, barrier function quasi-Newton, and bound constrained quasi-Newton (DAKOTA’s optpp.g.newton, optpp.ba.newton, and optpp.bc.newton methods), Gauss-Newton and bound constrained Gauss-Newton (DAKOTA’s optpp.g.newton and optpp.bc.newton methods - see Least Squares Methods), full Newton, barrier function full Newton, and bound constrained full Newton (DAKOTA’s optpp.newton, optpp.ba.newton, and optpp.bc.newton methods), finite difference Newton (DAKOTA’s optpp.fd.newton method), bound constrained ellipsoid (DAKOTA’s optpp.bc.ellipsis method), and full Newton, quasi-Newton, and finite difference Newton nonlinear interior point (DAKOTA’s optpp.nips, optpp.qnips, and optpp.fd.nips methods). The nonlinear interior point algorithms support general bound constraints, linear constraints, and general nonlinear constraints. The library also contains a direct search algorithm,
PDS (parallel direct search, DAKOTA's optpp_pds method). DAKOTA provides access to the OPT++ library through the SNLLOptimizer class, where “SNLL” denotes Sandia National Laboratories - Livermore.

5.7 OPT++ Methods

5.7.1 OPT++ method independent controls

The method independent controls for max_iterations and max_function_evaluations limit the number of major iterations and the number of function evaluations that can be performed during an OPT++ optimization. The convergence.tolerance control defines the threshold value on relative change in the objective function that indicates convergence. The output verbosity specification controls the amount of information generated by OPT++: the verbose and debug settings turn on OPT++’s internal debug mode. OPT++’s gradient-based methods are not parallel algorithms and cannot directly take advantage of concurrent function evaluations. However, if numerical_gradients with method_source dakota is specified, a parallel DAKOTA configuration can utilize concurrent evaluations for the finite difference gradient computations. OPT++’s nongradient-based PDS method can directly exploit asynchronous evaluations; however, this capability has not been implemented within DAKOTA V1.1.

The speculative specification enables speculative computation of gradient and/or Hessian information, where applicable, for parallel load balancing purposes. The specification is applicable to the computation of gradient information in cases where trust_region or value_based_line_search methods can be applied (see OPT++ method dependent controls for information on these options). The speculative specification must be used in conjunction with dakota numerical or analytic gradients. The specification is ignored and a warning message is printed for gradient computations when a gradient_based_line_search is used, or when the optpp_ba_newton, optpp_baq_newton or optpp_bc_ellipsoid methods are used. The speculative specification can also be applied to the full Newton methods, which require computation of analytic Hessians, or for the optpp_fd_newton method. However, the specification is ignored for the optpp_g_newton and optpp_bcg_newton Hessian computation, which approximates the Hessian from function and gradient values.

Lastly, specialized handling of linear constraints is supported by the nonlinear interior point methods (optpp_nips, optpp_q_nips, and optpp_fd_nips): all other OPT++ methods must be either unconstrained or, at most, bound-constrained. Specification detail for the method independent controls is provided in Tables 5.1 through 5.3.

5.7.2 OPT++ method dependent controls

OPT++’s method dependent controls are max_step, gradient.tolerance, search_method, initial_radius, merit_function, central_path, step_length_to_boundary, centering_parameter, and search_scheme_size. The max_step control specifies the maximum step that can be taken when computing a change in the current design point (e.g., limiting the Newton step computed from current gradient and Hessian information). It is equivalent to a move limit or a maximum trust region size. The gradient.tolerance control defines the threshold value on the L2 norm of the objective function gradient that indicates convergence to an unconstrained minimum (no active bound constraints). The gradient.tolerance control is defined for all gradient-based optimizers.

The search_method control is defined for all Newton-based optimizers and is used to select between trust_region, gradient_based_line_search, and value_based_line_search methods. The gradient_based_line_search option uses the line search method proposed by [More and Thuente, 1994]. The gradient_based_line_search option satisfies sufficient decrease and curvature conditions; whereas, value_based_line_search only satisfies the sufficient decrease
condition. At each line search iteration, the gradient-based line search method computes the function and gradient at the trial point. Consequently, given expensive function evaluations the value-based line search method is preferred to the gradient-based line search method.

The optpp_q_newton, optpp_newton, and optpp_fd_newton methods additionally support the tr_pds selection for performing a robust trust region search using pattern search techniques. Use of a line search is the default for barrier, bound-constrained, and nonlinear interior point methods, and use of a trust_region search method is the default for all others. The ellipsoid and barrier methods use built-in directional searches, and thus, the search_method control is not part of their specifications.

Table 5.6 covers the OPT++ conjugate gradient method specification. Table 5.7, Table 5.8, and Table 5.9 provide the details for the unconstrained, bound-constrained, and barrier function Newton-based methods, respectively.

Table 5.11 Specification detail for the OPT++ PDS method

The initial_radius control is defined for the ellipsoid method to specify the initial radius of the ellipsoid, and search_scheme_size is defined for the PDS method to specify the number of points to be used in the direct search template. Table 5.10 provides the detail for the bound constrained ellipsoid method and Table 5.11 provides the detail for the parallel direct search method.

The merit_function, central_path, steplengh_to_boundary, and centering-parameter specifications are defined for the OPT++ nonlinear interior point methods (optpp_nips, optpp_qnips, and optpp_fdnips). A merit_function is a function in constrained optimization that attempts to provide joint progress toward reducing the objective function and satisfying the constraints. Valid string inputs are "elbakry", "argaezapia", or "van_shanno", where user input is not case sensitive in this case. Details for these selections are as follows:
The "el\_bakry" merit function is the L2-norm of the first order optimality conditions for the nonlinear programming problem. The cost per linesearch iteration is n+1 function evaluations. For more information, see [El-Bakry et al., 1996].

The "argaez\_tapia" merit function can be classified as a modified augmented Lagrangian function. The augmented Lagrangian is modified by adding to its penalty term a potential reduction function to handle the perturbed complementarity condition. The cost per linesearch iteration is one function evaluation. For more information, see [Tapia and Argaez].

The "van\_shanno" merit function can be classified as a penalty function for the logarithmic barrier formulation of the nonlinear programming problem. The cost per linesearch iteration is one function evaluation. For more information see [Vandenberg and Shanno, 1999].

If the function evaluation is expensive or noisy, set the merit function to "argaez\_tapia" or "van\_shanno". The central\_path specification represents a measure of proximity to the central path and specifies an update strategy for the perturbation parameter \(\mu\). Refer to [Argaez et al., 2002] for a detailed discussion on proximity measures to the central region. Valid options are, again, "el\_bakry", "argaez\_tapia", or "van\_shanno", where user input is not case sensitive. The default value for central\_path is the value of merit\_function (either user-selected or default). The steplength\_to\_boundary specification is a parameter (between 0 and 1) that controls how close to the boundary of the feasible region the algorithm is allowed to move. A value of 1 means that the algorithm is allowed to take steps that may reach the boundary of the feasible region. If the user wishes to maintain strict feasibility of the design parameters this value should be less than 1. Default values are .8, .99995, and .95 for the "el\_bakry", "argaez\_tapia", and "van\_shanno" merit functions, respectively. The centering\_parameter specification is a parameter (between 0 and 1) that controls how closely the algorithm should follow the "central path". See [Wright] for the definition of central path. The larger the value, the more closely the algorithm follows the central path, which results in small steps. A value of 0 indicates that the algorithm will take a pure Newton step. Default values are .2, .2, and .1 for the "el\_bakry", "argaez\_tapia", and "van\_shanno" merit functions, respectively. Table 5.12 provides the detail for the nonlinear interior point methods.

Table 5.12 Specification detail for the OPT++ nonlinear interior point methods
5.8 Asynchronous Parallel Pattern Search Method

Pattern search techniques are nongradient-based optimization methods which use a set of offsets from the current iterate to locate improved points in the design space. The asynchronous parallel pattern search (APPS) algorithm [Hough et al., 2000] is a fully asynchronous pattern search technique, in that the search along each offset direction continues without waiting for searches along other directions to finish. It utilizes the nonblocking schedulers in DAKOTA (see DakodaModel::synchronize_nowait()).
5.8.1 APPS method independent controls

The only method independent control currently mapped to APPS is the output verbosity control. The APPS internal "debug" and "profile" levels are mapped to the DAKOTA debug, verbose, normal, and quiet settings as follows:

- DAKOTA "debug": APPS debug level = 10, profile level = 1
- DAKOTA "verbose": APPS debug level = 10, profile level = 1
- DAKOTA "normal": APPS debug level = 2, profile level = 1
- DAKOTA "quiet": APPS debug level = 0, profile level = 0

5.8.2 APPS method dependent controls

The APPS method is invoked using an apps group specification. Components within this specification group include initial_delta, threshold_delta, pattern_basis, total_pattern_size, no_expansion, and contraction_factor. The initial_delta and threshold_delta specifications are required in order to provide the initial offset size and the threshold size at which to terminate the algorithm, respectively. These sizes are dimensional and are not relative to the bounded region (as they are with sgopt_pattern_search). The pattern_basis specification is used to select between a coordinate basis or a simplex basis. The former uses a plus and minus offset in each coordinate direction, for a total of $2n$ function evaluations in the pattern, whereas the latter uses a minimal positive basis simplex for the parameter space, for a total of $n+1$ function evaluations in the pattern. The total_pattern_size specification can be used to augment the basic coordinate and simplex patterns with additional function evaluations, and is particularly useful for parallel load balancing. For example, if some function evaluations in the pattern are dropped due to duplication or bound constraint interaction, then the total_pattern_size specification instructs the algorithm to generate new offsets to bring the total number of evaluations up to this consistent total. The no_expansion flag instructs the algorithm to omit pattern expansion, which is normally performed after a sequence of improving offsets is found. Finally, the contraction_factor specification selects the scaling factor used in computing a reduced offset for a new pattern search cycle after the previous cycle has been unsuccessful in finding an improved point. Table 5.13 summarizes the APPS specification.

5.9 SGOPT Methods

The SGOPT (Stochastic Global OPTimization) library [Hart, W.E., 2001a; Hart, W.E., 2001b] contains a variety of nongradient-based optimization algorithms, with an emphasis on stochastic global methods. SGOPT currently includes the following global optimization methods: evolutionary algorithms (\texttt{sgopt\_pga\_real}, \texttt{sgopt\_pga\_int}, and \texttt{sgopt\_epsa}) and stratified Monte Carlo (\texttt{sgopt\_strat\_mc}). Additionally, SGOPT includes nongradient-based local search algorithms such as Solis-Wets (\texttt{sgopt\_solis\_wets}) and pattern search (\texttt{sgopt\_pattern\_search}). DAKOTA provides access to the SGOPT library through the \texttt{SGOPTOptimzer} class.

5.9.1 SGOPT method independent controls

The method independent controls for \texttt{max\_iterations} and \texttt{max\_function\_evaluations} limit the number of major iterations and the number of function evaluations that can be performed during an SGOPT optimization. The \texttt{convergence\_tolerance} control defines the threshold value on relative change in the objective function that indicates convergence. The \texttt{output\_verbosity} specification controls the amount of information generated by SGOPT: the \texttt{quiet} and \texttt{normal} settings correspond to minimal reporting from SGOPT, whereas the \texttt{verbose} setting corresponds to a higher level of information, and \texttt{debug} outputs method initialization and a variety of internal SGOPT diagnostics. The majority of SGOPT’s methods have independent function evaluations that can directly take advantage of DAKOTA’s parallel capabilities. Only \texttt{sgopt\_solis\_wets} is inherently serial. The parallel methods automatically utilize parallel logic when the DAKOTA configuration supports parallelism. Note that parallel usage of \texttt{sgopt\_pattern\_search} overrides any setting for exploratory moves (see \texttt{Pattern search}), since the \texttt{multi\_step}, \texttt{best\_first}, \texttt{biased\_best\_first}, and \texttt{adaptive\_pattern} settings only involve relevant distinctions for the case of serial operation. Lastly, neither speculative gradients nor specialized handling of linear constraints are currently supported with SGOPT since SGOPT methods are nongradient-based and support, at most, bound constraints. Specification detail for method independent controls is provided in Tables 5.1 through 5.3.

5.9.2 SGOPT method dependent controls

\texttt{solution\_accuracy} and \texttt{max\_cpu\_time} are method dependent controls which are defined for all SGOPT methods. Solution accuracy defines a convergence criterion in which the optimizer will terminate if it finds an objective function value lower than the specified accuracy. Note that the default of 1.e-5 should be overridden in those applications where it could cause premature termination. The maximum CPU time setting is another convergence criterion in which the optimizer will terminate if its CPU usage in seconds exceeds the specified limit. Table 5.14 provides the specification detail for these recurring method dependent controls.

<table>
<thead>
<tr>
<th>Description</th>
<th>Keyword</th>

</tr>
</tbody>
</table>

Each SGOPT method supplements the settings of Table 5.14 with controls which are specific to its particular class of method.
5.9.3 Evolutionary Algorithms

DAKOTA currently provides three types of evolutionary algorithms (EAs): a real-valued genetic algorithm (sgopt+pga+real), an integer-valued genetic algorithm (sgopt+pga+int), and an evolutionary pattern search technique (sgopt+epsa), where "real-valued" and "integer-valued" refer to the use of continuous or discrete variable domains, respectively (the response data are real-valued in all cases).

The basic steps of an evolutionary algorithm are as follows:

1. Select an initial population randomly and perform function evaluations on these individuals

2. Perform selection for parents based on relative fitness

3. Apply crossover and mutation to generate new solutions generated new individuals from the selected parents
   - Apply crossover with a fixed probability from two selected parents
   - If crossover is applied, apply mutation to the newly generated individual with a fixed probability
   - If crossover is not applied, apply mutation with a fixed probability to a single selected parent

4. Perform function evaluations on the new individuals

5. Perform replacement to determine the new population

6. Return to step 2 and continue the algorithm until convergence criteria are satisfied or iteration limits are exceeded

Controls for seed, population size, selection, and replacement are identical for the three EA methods, whereas the crossover and mutation controls contain slight differences and the sgopt+epsa specification contains an additional num_partitions input. Table 5.15 provides the specification detail for the controls which are common between the three EA methods.

Table 5.15 Specification detail for the SGOPT EA methods
The random seed control provides a mechanism for making a stochastic optimization repeatable. That is, the use of the same random seed in identical studies will generate identical results. The population size control specifies how many individuals will comprise the EA's population. The selection pressure controls how strongly differences in "fitness" (i.e., the objective function) are weighted in the process of selecting "parents" for crossover:

- the rank setting uses a linear scaling of probability of selection based on the rank order of each individual's objective function within the population

- the proportional setting uses a proportional scaling of probability of selection based on the relative value of each individual's objective function within the population

The replacement type controls how current populations and newly generated individuals are combined to create a new population. Each of the replacement type selections accepts an integer value, which will be referred to below and in Table 5.15 as the replacement size:

- The random setting (the default) creates a new population using (a) replacement size randomly selected individuals from the current population, and (b) population size - replacement size individuals randomly selected from among the newly generated individuals (the number of which is optionally specified using new solutions generated) that are created for each generation (using the selection, crossover, and mutation procedures).

- The CHC setting creates a new population using (a) the replacement size best individuals from the combination of the current population and the newly generated individuals, and (b) population size - replacement size individuals randomly selected from among the remaining individuals in this combined pool. CHC is the preferred selection for many engineering problems.
• The elitist setting creates a new population using (a) the `replacement_size` best individuals from the current population, (b) and `population_size - replacement_size` individuals randomly selected from the newly generated individuals. It is possible in this case to lose a good solution from the newly generated individuals if it is not randomly selected for replacement; however, the default `new_solutions_generated` value is set such that the entire set of newly generated individuals will be selected for replacement.

Table 5.16, Table 5.17, and Table 5.18 show the controls which differ between `sgopt_pga_real`, `sgopt_pga_int`, and `sgopt_epsa`, respectively.

The crossover_type controls what approach is employed for combining parent genetic information to create offspring, and the crossover_rate specifies the probability of a crossover operation being performed to generate a new offspring. SGOPT supports two generic forms of crossover, two_point and uniform, which generate a new individual through coordinate-wise combinations of two parent individuals. Two-point crossover divides each parent into three regions, where offspring are created from the combination of the middle region from one parent and the end regions from the other parent. Since SGOPT does not utilize bit representations of variable values, the crossover points only occur on coordinate boundaries, never within the bits of a particular coordinate. Uniform crossover creates offspring through random combination of coordinates from the two parents. The sgopt_pga_real optimizer supports a third option, the blend crossover method, which generates a new individual randomly along the multidimensional vector connecting the two parents.

The mutation_type controls what approach is employed in randomly modifying design variables within the EA population. Each of the mutation methods generates coordinate-wise changes to individuals, usually by adding a random variable to a given coordinate value (an "offset" mutation), but also by replacing a given coordinate value with a random variable (a "replace" mutation). The population_rate controls the probability of mutation being performed on an individual, both for new individuals generated by crossover (if crossover occurs) and for individuals from the existing population (if crossover does not occur; see algorithm description in Evolutionary Algorithms). The dimension_rate specifies the probabilities that a given dimension is changed given that the individual is having mutation applied to it. The default dimension_rate uses the special formula shown in the preceding tables, where \(n\) is the number of design variables and \(e\) is the natural logarithm constant. The mutation_scale specifies a scale factor which scales mutation offsets for sgopt_pga_real and sgopt_pgsa; this is a fraction of the total range of each dimension, so mutation_scale is a relative value between 0 and 1. The mutation_range provides an analogous control for sgopt_pga_int, but is not a relative value in that it specifies the total integer range of the mutation. The offset_normal, offset_cauchy, offset_uniform, and offset_triangular mutation types are "offset" mutations in that they add a 0-mean random variable with a normal, cauchy, uniform, or triangular distribution, respectively, to the existing coordinate value. These offsets are limited in magnitude by mutation_scale. The replace_uniform mutation type
is not limited by mutation_scale; rather it generates a replacement value for a coordinate using a uniformly distributed value over the total range for that coordinate. The real-valued genetic algorithm supports each of these 5 mutation types, and integer-valued genetic algorithm supports the replace uniform and offset uniform types. The mutation types for evolutionary pattern search are more specialized:

- **multi_coord**: Mutate each coordinate dimension with probability dimension_rate using an "offset" approach with initial scale mutation_scale * variable range. Multiple coordinates may or may not be mutated.

- **unary_coord**: Mutate a single randomly selected coordinate dimension using an "offset" approach with initial scale mutation_scale * variable range. One and only one coordinate is mutated.

- **multi_simplex**: Apply each of the vector offsets from a regular simplex (n+1 vectors for n dimensions) with probability dimension_rate and initial scale mutation_scale * variable range. A single vector offset may alter multiple coordinate dimensions. Multiple simplex vectors may or may not be applied.

- **unary_simplex**: Add a single randomly selected vector offset from a regular simplex with an initial scale of mutation_scale * variable range. One and only one simplex vector is applied, but this simplex vector may alter multiple coordinate dimensions.

and are described in more detail in [Hart and Hunter, 1999]. Both the real-valued genetic algorithm and the evolutionary pattern search algorithm use adaptive mutation that modifies the mutation scale dynamically. The non_adaptive flag can be used to deactivate the self-adaptation in real-valued genetic algorithms, which may facilitate a more global search. The adaptive mutation in evolutionary pattern search is an inherent component that cannot be deactivated. The min_scale input specifies the minimum mutation scale for evolutionary pattern search; sgopt_epsa terminates if the adapted mutation scale falls below this threshold.

The num_partitions specification is not part of the crossover or mutation group specifications; it specifies the number of possible values for each dimension (fractions of the variable ranges) used in the initial evolutionary pattern search population. It is needed for theoretical reasons.

For additional information on these options, see the user and reference manuals for SGOPT [Hart, 2001a; Hart, 2001b].

### 5.9.4 Pattern search

SGOPT provides a pattern search technique (sgopt_pattern_search) whose operation and controls are similar to that of APPS (see Asynchronous Parallel Pattern Search Method). Table 5.19 provides the specification detail for the SGOPT PS method and its method dependent controls.

**Table 5.19 Specification detail for the SGOPT pattern search method**

</table>

The `initial_delta`, `threshold_delta`, `pattern_basis`, `total_pattern_size`, `no_expansion`, and `contraction_factor` controls are identical in meaning to the corresponding APPS controls (see Asynchronous Parallel Pattern Search Method). Differing controls include the stochastic, seed, expand_after_success, and exploratory_moves specifications. The SGOPT pattern search provides the capability for stochastic shuffling of offset evaluation order, for which the random seed can be used to make the optimizations repeatable. The expand_after_success control specifies how many successful objective function improvements must occur with a specific delta prior to expansion of the delta.

The exploratory_moves setting controls how the offset evaluations are ordered as well as the logic for acceptance of an improved point. The following exploratory moves selections are supported by SGOPT:

- **The multi_step case** examines each trial step in the pattern in turn. If a successful step is found, the pattern search continues examining trial steps about this new point. In this manner, the effects of multiple successful steps are cumulative within a single iteration.

- **The best_all case** waits for completion of all offset evaluations in the pattern before selecting a new iterate. This method is most appropriate for parallel execution of the pattern search.

- **The best_first case** immediately selects the first improving point found as the new iterate, with-
out waiting for completion of all offset evaluations in the cycle.

- The biased_bf first case immediately selects the first improved point as the new iterate, but also introduces a bias toward directions in which improving points have been found previously by reordering the offset evaluations.

- The adaptive_pattern case invokes a pattern search technique that adaptively rescales the different search directions to maximize the number of redundant function evaluations. See [Hart et al., 2001] for details of this method. In preliminary experiments, this method had more robust performance than the standard best_first case.

- The test case is used for development purposes. This currently utilizes a nonblocking scheduler (i.e., DakotaModel::synchronize_nowait()) for performing the function evaluations.

### 5.9.5 Solis-Wets

DAKOTA's implementation of SGOPT also contains the Solis-Wets algorithm. The Solis-Wets method is a simple greedy local search heuristic for continuous parameter spaces. Solis-Wets generates trial points using a multivariate normal distribution, and unsuccessful trial points are reflected about the current point to find a descent direction. This algorithm is inherently serial and will not utilize any parallelism. Table 5.20 provides the specification detail for this method and its method dependent controls.

**Table 5.20 Specification detail for the SGOPT Solis-Wets method**

The seed, initial_delta, threshold_delta, no_expansion, expand_after_success, and contraction_factor specifications have identical meaning to the corresponding specifications for apps and sgopt_pattern_search (see Asynchronous Parallel Pattern Search Method and...
Pattern search). The only new specification is `contract_after_failure`, which specifies the number of unsuccessful cycles which must occur with a specific delta prior to contraction of the delta.

### 5.9.6 Stratified Monte Carlo

Lastly, DAKOTA’s implementation of SGOPT contains a stratified Monte Carlo (sMC) algorithm. One of the distinguishing characteristics of this sampling technique from other sampling methods in Design of Computer Experiments Methods and Nondeterministic sampling method is its stopping criteria. Using `solution_accuracy` (see SGOPT method dependent controls), the sMC algorithm can terminate adaptively when a design point with a desired performance has been located. Table 5.21 provides the specification detail for this method and its method dependent controls.

**Table 5.21 Specification detail for the SGOPT sMC method**

<table>
<thead>

<td>1</td>
</tr>
<tr>
<td>Partitions per variable</td>
<td><code>partitions</code></td>
<td>list of integers</td>
<td>Optional</td>
<td>No partitioning</td>
</tr>
</tbody>
</table>

As for other SGOPT methods, the random `seed` is used to make stochastic optimizations repeatable. The `batch_size` input specifies the number samples to be evaluated in each multidimensional partition. And the `partitions` list is used to specify the number of partitions for each design variable. For example, `partitions = 2, 4, 3` specifies 2 partitions in the first design variable, 4 partitions in the second design variable, and 3 partitions in the third design variable. This creates a total of 24 multidimensional partitions, and a `batch_size` of 2 would select 2 random samples in each partition, for a total of 48 samples on each iteration of the sMC algorithm. Iterations containing 48 samples will continue until the maximum number of iterations or function evaluations is exceeded, or the desired solution accuracy is obtained.

### 5.10 Least Squares Methods

The Gauss-Newton algorithm is available from the OPT++ library as either `optpp_g_newton` or `optpp_bcg_newton`, where the latter adds bound constraint support. The code for the Gauss-Newton approximation (objective function value, gradient, and approximate Hessian defined from residual function values and gradients) is available in `SNLLOptimizer::nlf2_evaluator_gn()`. The important difference with these algorithms is that the response set must involve least squares terms, rather than an objective function. Thus, a lower granularity of data must be returned to least squares solvers in comparison to the data returned to optimizers. Refer to Least squares terms (least squares data set) for additional information on the least squares response data set.

Mappings for the method independent controls are as described in OPT++ method independent controls, and the `search_method`, `max_step`, and `gradient_tolerance` controls are as described in...
**OPT++ method dependent controls.** Table 5.22 provides the details for the Gauss-Newton least squares methods.

**5.11 Nondeterministic Methods**

DAKOTA's nondeterministic branch does not currently make use of any method independent controls. As such, the nondeterministic branch documentation which follows is limited to the method dependent controls for the sampling, analytic reliability, and polynomial chaos expansion methods.

**5.11.1 Nondeterministic sampling method**

The nondeterministic sampling iterator is selected using the `nond_sampling` specification. This iterator performs sampling within specified parameter distributions in order to assess the distributions for response functions. Probability of event occurrence (e.g., failure) is then assessed by comparing the response results against response thresholds. DAKOTA currently provides access to nondeterministic sampling methods within the `NonDProbability` class.

The `seed` integer specification specifies the seed for the random number generator which is used to make sampling studies repeatable. The number of samples to be evaluated is selected with the `samples` integer specification. The algorithm used to generate the samples can be specified using `sample_type` followed by either `random`, for pure random Monte Carlo sampling, or `lhs`, for latin hypercube sampling. The `response_thresholds` specification supplies a list of thresholds for comparison with the response functions being computed. Statistics on responses above and below these thresholds are then generated.

The nondeterministic sampling iterator also supports a design of experiments mode through the `all_variables` flag. Normally, `nond_sampling` generates samples only for the uncertain variables, and treats any design or state variables as constants. The `all_variables` flag alters this behavior by instructing the sampling algorithm to treat any continuous design or continuous state variables as parameters with uniform probability distributions between their upper and lower bounds. Samples are then generated over all of the continuous variables (design, uncertain, and state) in the variables specification. This is similar to
the behavior of the design of experiments methods described in *Design of Computer Experiments Methods*, since they will also generate samples over all continuous design, uncertain, and state variables in the variables specification. However, the design of experiments methods will treat all variables as being uniformly distributed between their upper and lower bounds, whereas the *nond_sampling* iterator will sample the uncertain variables within their specified probability distributions. Table 5.23 provides the specification detail for the sampling methods.

5.11.2 Analytic reliability methods

Analytic reliability methods are selected using the *nond_analytic_reliability* specification. This iterator computes approximate response function distribution statistics based on specified parameter distributions. Analytic reliability methods perform an internal nonlinear optimization to compute a most probable point (MPP) and then integrate about this point to compute probabilities. Supported techniques include the Mean Value method (MV), Advanced Mean Value method (AMV), an iterated form of AMV (AMV+), first order reliability method (FORM), and second order reliability method (SORM), which are selected using the *mv*, *amv*, *iterated_amv*, *form*, and *sorm* specifications, respectively. Each of these methods involves a required group specification, separated by OR’s. All of the techniques support a *response_levels* specification, which provide the target response values for generating probabilities. In combination, these response level probabilities provide a cumulative distribution function, or CDF, for a response function. The AMV+ method additionally supports a *probability_levels* option, which iterates to find the response level which corresponds to a specified probability (the inverse of the *response_levels* problem). Table 5.24 provides the specification detail for these methods.

### 5.11.3 Polynomial chaos expansion method

The polynomial chaos expansion method is a general framework for the approximate representation of random response functions in terms of finite dimensional series expansions in standard unit Gaussian random variables. An important distinguishing feature of the methodology is that the solution series expansions are expressed as random processes not merely as statistics as in the case of many nondeterministic methodologies.

The method requires either the `expansion_terms` or the `expansion_order` specification in order to specify the number of terms in the expansion or the highest order of Gaussian variable appearing in the expansion. The number of terms, $P$, in a complete polynomial chaos expansion of arbitrary order, $p$, for a response function involving $n$ uncertain input variables is given by

$$P = 1 + \sum_{s=1}^{p} \frac{1}{s!} \prod_{r=0}^{s-1} (n + r).$$

One must be careful when using the `expansion_terms` specification, as the satisfaction of the above equation for some order $p$ is not rigidly enforced. As a result, in some cases, only a subset of terms of a certain order will be included in the series while others of the same order will be omitted. This omission of terms can increase the efficacy of the methodology for some problems but have extremely deleterious effects for others. The method outputs either the first `expansion_terms` coefficients of the series or the coefficients of all terms up to order `expansion_order` in the series depending on the specification. The `seed`, `samples`, `sample_type`, and `response_thresholds` specifications are used to specify settings for an internal invocation of the `NonDProbability` sampling techniques. Refer to `Nondeterministic sampling method` for information on these specifications. Table 5.25 provides the specification detail for the polynomial chaos expansion method.

### Table 5.25 Specification detail for polynomial chaos expansion method
5.12 Design of Computer Experiments Methods

The Distributed Design and Analysis of Computer Experiments (DDACE) library provides design of experiments methods for computing response data sets at a selection of points in the parameter space. Current techniques include grid sampling (grid), pure random sampling (random), orthogonal array sampling (oas), latin hypercube sampling (lhs), orthogonal array latin hypercube sampling (oa_lhs), Box-Behnken (box_behnken_design), and central composite design (central_composite_design). It is worth noting that there is some overlap in sampling techniques with those available from the nondeterministic branch. The current distinction is that the nondeterministic branch methods are designed to sample within a variety of probability distributions for uncertain variables, whereas the design of experiments methods treat all variables as having uniform distributions. As such, the design of experiments methods are well-suited for performing parametric studies and for generating data sets used in building global approximations (see Global approximation interface), but are not designed for assessing the effect of uncertainties. If a design of experiments over both design/state variables (treated as uniform) and uncertain variables (with probability distributions) is desired, then nond_sampling can support this with its all_variables option (see Nondeterministic sampling method). DAKOTA provides access to the DDACE library through the DACEIterator class.

The design of experiments methods do not currently make use of any of the method independent controls. In terms of method dependent controls, the specification structure is straightforward. First, there is a set of design of experiments algorithm selections separated by logical OR's (grid or random or oas or lhs or oa_lhs or box_behnken_design or central_composite_design). Second, there are optional specifications for the random seed to use in generating the sample set (seed), the number of samples to perform (samples), and the number of symbols to use (symbols). The seed control is used to make sample sets repeatable, and the symbols control is related to the number of replications in the sample set (a larger number of symbols equates to more stratification and fewer replications). Design of experiments specification detail is given in Table 5.26.

5.13 Parameter Study Methods

DAKOTA's parameter study methods compute response data sets at a selection of points in the parameter space. These points may be specified as a vector, a list, a set of centered vectors, or a multi-dimensional grid. Capability overviews and examples of the different types of parameter studies are provided in the Users Manual. DAKOTA implements all of the parameter study methods within the **ParamStudy** class.

DAKOTA's parameter study methods do not currently make use of any of the method independent controls. Therefore, the parameter study documentation which follows is limited to the method dependent controls for the vector, list, centered, and multidimensional parameter study methods.

5.13.1 Vector parameter study

DAKOTA's vector parameter study computes response data sets at selected intervals along a vector in parameter space. It is often used for single-coordinate parameter studies (to study the effect of a single variable on a response set), but it can be used more generally for multiple coordinate vector studies (to investigate the response variations along some n-dimensional vector). This study is selected using the **vector_parameter_study** specification followed by either a **final_point** or a **step_vector** specification.

The vector for the study can be defined in several ways (refer to **dakota.input.spec**). First, a **final_point** specification, when combined with the initial values from the variables specification (see **cdv_initial_point**, **ddv_initial_point**, **csv_initial_state**, and **dsv_initial_state** in **Variables Commands**), uniquely defines an n-dimensional vector's direction and magnitude through its start and end points. The intervals along this vector may either be specified with a **step_length** or a **num_steps** specification. In the former case, steps of equal length (Cartesian distance) are taken from the initial values up to (but not past) the **final_point**. The study will terminate at the last full step which does not go beyond the **final_point**. In the latter **num_steps** case, the distance between the initial values and the **final_point** is broken into **num_steps** intervals of equal length. This study performs function evaluations at both ends, making the total number of evaluations equal to **num_steps+1**. The **final_point** specification detail is given in...
Table 5.27.

Table 5.27 final_point specification detail for the vector parameter study

</tr>
</tbody>
</table>

The other technique for defining a vector in the study is the step_vector specification. This parameter study begins at the initial values and adds the increments specified in step_vector to obtain new simulation points. This process is performed num_steps times, and since the initial values are included, the total number of simulations is again equal to num_steps+1. The step_vector specification detail is given in Table 5.28.

5.13.2 List parameter study

DAKOTA’s list parameter study allows for evaluations at user selected points of interest which need not follow any particular structure. This study is selected using the list_parameter_study method specification followed by a list_of_points specification.

The number of real values in the list_of_points specification must be a multiple of the total number of continuous variables contained in the variables specification. This parameter study simply performs simulations for the first parameter set (the first n entries in the list), followed by the next parameter set (the next n entries), and so on, until the list of points has been exhausted. Since the initial values from the variables specification will not be used, they need not be specified. The list parameter study specification detail is given in Table 5.29.

5.13.3 Centered parameter study

DAKOTA’s centered parameter study computes response data sets along multiple vectors, one per parameter, centered about the initial values from the variables specification. This is useful for investigation of function contours with respect to each parameter individually in the vicinity of a specific point (e.g., post-optimality analysis for verification of a minimum). It is selected using the \texttt{centered\_parameter\_study} method specification followed by \texttt{percent\_delta} and \texttt{deltas\_per\_variable} specifications, where \texttt{percent\_delta} specifies the size of the increments in percent and \texttt{deltas\_per\_variable} specifies the number of increments per variable in each of the plus and minus directions. The centered parameter study specification detail is given in Table 5.30.

5.13.4 Multidimensional parameter study

DAKOTA’s multidimensional parameter study computes response data sets for an n-dimensional grid of points. Each continuous variable is partitioned into equally spaced intervals between its upper and lower bounds, and each combination of the values defined by the boundaries of these partitions is evaluated. This study is selected using the \texttt{multidim\_parameter\_study} method specification followed by a \texttt{partitions} specification, where the \texttt{partitions} list specifies the number of partitions for each continuous variable. Therefore, the number of entries in the partitions list must be equal to the total number of continuous variables contained in the variables specification. Since the initial values from the variables specification will not be used, they need not be specified. The multidimensional parameter study specification detail is given in Table 5.31.

Chapter 6

Variables Commands

6.1 Variables Description

The variables section in a DAKOTA input file specifies the parameter set to be iterated by a particular method. This parameter set is made up of design, uncertain, and state variable specifications. Design variables can be continuous or discrete and consist of those variables which an optimizer adjusts in order to locate an optimal design. Each of the design parameters can have an initial point, a lower bound, an upper bound, and a descriptive tag. Uncertain variables are continuous variables which are characterized by probability distributions. The distribution type can be normal, lognormal, uniform, loguniform, weibull, or histogram. Each uncertain variable specification can contain a distribution lower bound, a distribution upper bound, and a descriptive tag. Normal variables also include mean and standard deviation specifications, lognormal variables include mean, standard deviation, and error factor specifications, weibull variables include alpha and beta specifications, and histogram variables include file name specifications. State variables can be continuous or discrete and consist of “other” variables which are to be mapped through the simulation interface. Each state variable specification can have an initial state, lower and upper bounds, and a descriptor. State variables provide a convenient mechanism for parameterizing additional model inputs, such as mesh density, simulation convergence tolerances and time step controls, and will be used to enact model adaptivity in future strategy developments.

Several examples follow. In the first example, two continuous design variables are specified:

```
variables,
    continuous_design = 2
    cdv_initial_point 0.9 1.1
    cdv_upper_bounds  5.8 2.9
    cdv_lower_bounds  0.5 -2.9
    cdv_descriptor 'radius' 'location'
```

In the next example, defaults are employed. In this case, cdv_initial_point will default to a vector of 0.0 values, cdv_upper_bounds will default to vector values of DBL_MAX (defined in the float.h C header file), cdv_lower_bounds will default to a vector of -DBL_MAX values, and cdv_descriptor will default to a vector of ‘cdv_i’ strings, where i ranges from one to two:

```
variables,
    continuous_design = 2
```
In the following example, the syntax for a normal-lognormal distribution is shown. One normal and one lognormal uncertain variable are completely specified by their means and standard deviations. In addition, the dependence structure between the two variables is specified using the uncertain_correlation_matrix.

variables,
    normal_uncertain = 1
    nuv_means = 1.0
    nuv_std_deviations = 1.0
    nuv_descriptor = 'TF1n'
    lognormal_uncertain = 1
    lnuv_means = 2.0
    lnuv_std_deviations = 0.5
    lnuv_descriptor = 'TF2ln'
    uncertain_correlation_matrix = 1.0 0.2
    0.2 1.0

An example of the syntax for a state variables specification follows:

variables,
    continuous_state = 1
    csv_initial_state 4.0
    csv_lower_bounds 0.0
    csv_upper_bounds 8.0
    csv_descriptor 'CS1'
    discrete_state = 1
    dsv_initial_state 104
    dsv_lower_bounds 100
    dsv_upper_bounds 110
    dsv_descriptor 'DS1'

And in an advanced example, a variables specification containing a set identifier, continuous and discrete design variables, normal and uniform uncertain variables, and continuous and discrete state variables is shown:

variables,
    id_variables = 'V1'
    continuous_design = 2
    cdv_initial_point 0.9 1.1
    cdv_upper_bounds 5.8 2.9
    cdv_lower_bounds 0.5 -2.9
    cdv_descriptor 'radius' 'location'
    discrete_design = 1
    ddv_initial_point 2
    ddv_upper_bounds 1
    ddv_lower_bounds 3
    ddv_descriptor 'material'
    normal_uncertain = 2
    nuv_means = 248.89, 593.33
    nuv_std_deviations = 12.4, 29.7
    nuv_descriptor = 'TF1n' 'TF2n'
    uniform_uncertain = 2
    uuv_dist_lower_bounds = 199.3, 474.63
    uuv_dist_upper_bounds = 298.5, 712.
    uuv_descriptor = 'TF1u' 'TF2u'
    continuous_state = 2
    csv_initial_state = 1.e-4 1.e-6
    csv_descriptor = 'EPSIT1' 'EPSIT2'
    discrete_state = 1
    dsv_initial_state = 100
    dsv_descriptor = 'load_case'
Refer to the DAKOTA Users Manual [Eldred et al., 2001] for discussion on how different iterators view these mixed variable sets.

### 6.2 Variables Specification

The variables specification has the following structure:

```plaintext
variables,
  <set identifier>   
  <continuous design variables specification> 
  <discrete design variables specification> 
  <normal uncertain variables specification> 
  <lognormal uncertain variables specification> 
  <uniform uncertain variables specification> 
  <loguniform uncertain variables specification> 
  <weibull uncertain variables specification> 
  <histogram uncertain variables specification> 
  <uncertain correlation specification> 
  <continuous state variables specification> 
  <discrete state variables specification>
```

Referring to `dakota.input.spec`, it is evident from the enclosing brackets that the set identifier specification and the continuous design, discrete design, normal uncertain, lognormal uncertain, uniform uncertain, loguniform uncertain, weibull uncertain, histogram uncertain, continuous state, and discrete state variables specifications are all optional. The set identifier is a stand-alone optional specification, whereas the latter ten are optional group specifications, meaning that the group can either appear or not as a unit. If any part of an optional group is specified, then all required parts of the group must appear.

The optional set identifier can be used to provide a unique identifier string for labeling a particular variables specification. A method can then identify the use of a particular set of variables by specifying this label in its `variables_pointer` specification (see Method Independent Controls). The optional status of the different variable type specifications allows the user to specify only those variables which are present (rather than explicitly specifying that the number of a particular type of variables = 0). However, at least one type of variables must have nonzero size or an input error message will result. The following sections describe each of these specification components in additional detail.

### 6.3 Variables Set Identifier

The optional set identifier specification uses the keyword `id_variables to input a string for use in identifying a particular variables set with a particular method (see also `variables_pointer in Method Independent Controls`). For example, a method whose specification contains `variables_pointer = 'V1'` will use a variables set with `id_variables = 'V1'.`

If the set identifier specification is omitted, a particular variables set will be used by a method only if that method omits specifying `variables_pointer` and if the variables set was the last set parsed (or is the only set parsed). In common practice, if only one variables set exists, then `id_variables` can be safely omitted from the variables specification and `variables_pointer` can be omitted from the method specification(s), since there is no potential for ambiguity in this case. Table 6.1 summarizes the set identifier inputs.

**Table 6.1 Specification detail for set identifier**

6.4 Design Variables

Within the optional continuous design variables specification group, the number of continuous design variables is a required specification and the initial guess, lower bounds, upper bounds, and variable names are optional specifications. Likewise, within the optional discrete design variables specification group, the number of discrete design variables is a required specification and the initial guess, lower bounds, upper bounds, and variable names are optional specifications. Table 6.2 summarizes the details of the continuous design variable specification and Table 6.3 summarizes the details of the discrete design variable specification.

</table>

The cdv_initial_point and ddv_initial_point specifications provide the point in design space from which an iterator is started for the continuous and discrete design variables, respectively. The cdv_lower_bounds, ddv_lower_bounds, cdv_upper_bounds and ddv_upper_bounds restrict the size of the feasible design space and are frequently used to prevent nonphysical designs. The cdv_descriptor and ddv_descriptor specifications supply strings which will be replicated through the DAKOTA output to help identify the numerical values for these parameters. Default values for optional
specifications are zeros for initial values, positive and negative machine limits for upper and lower bounds
(+/-DBL_MAX, INT_MAX, INT_MIN from the float.h and limits.h system header files), and numbered strings for descriptors.

6.5 Uncertain Variables

Uncertain variables involve one of several supported probability distribution specifications, including normal, lognormal, uniform, loguniform, weibull, or histogram distributions. Each of these specifications is an optional group specification. Within the normal uncertain optional group specification, the number of normal uncertain variables, the means, and standard deviations are required specifications, and the distribution lower and upper bounds and variable descriptors are optional specifications. Within the lognormal uncertain optional group specification, the number of lognormal uncertain variables, the means, and either standard deviations or error factors must be specified, and the distribution lower and upper bounds and variable descriptors are optional specifications. Within the uniform uncertain optional group specification, the number of uniform uncertain variables and the distribution lower and upper bounds are required specifications, and variable descriptors is an optional specification. Within the loguniform uncertain optional group specification, the number of loguniform uncertain variables and the distribution lower and upper bounds are required specifications, and variable descriptors is an optional specification. Within the weibull uncertain optional group specification, the number of weibull uncertain variables and the alpha and beta parameters are required specifications, and the distribution lower and upper bounds and variable descriptors are optional specifications. And finally, within the histogram uncertain optional group specification, the number of histogram uncertain variables and file names are required specifications, and the distribution lower and upper bounds and variable descriptors are optional specifications. Tables 6.4 through 6.9 summarize the details of the uncertain variable specifications.

Lower and upper distribution bounds can be used to truncate the tails of the distributions for those distributions for which bounds are meaningful. They are provided for all distribution types in order to support methods which rely on a bounded region to define a set of function evaluations (i.e., design of experiments and some parameter study methods). Default bounds are positive and negative machine limits (+/-DBL_MAX) defined in the float.h system header file. The uncertain variable descriptor specifications provides strings which will be replicated through the DAKOTA output to help identify the numerical values for these parameters. Default values for descriptors are numbered strings.

Uncertain variables may have correlations specified through use of an uncertain_correlation_matrix specification. This specification is generalized in the sense that its specific meaning depends on the nondeterministic method in use. When the method is a nondeterministic sampling method (i.e., nond_sampling), then the correlation matrix specifies rank correlations [Iman and Conover, 1982]. When the method is instead an analytic reliability (i.e., nond_analytic_reliability) or polynomial chaos (i.e., nond_polynomial_chaos) method, then the correlation matrix specifies correlation coefficients (normalized covariance) [Haldar and Mahadevan, 2000]. In either of these cases, specifying the identity matrix results in uncorrelated uncertain variables (the default). The matrix input should have \( n^2 \) entries listed by rows where \( n \) is the total number of uncertain variables (all normal, lognormal, uniform, loguniform, weibull, and histogram specifications, in that order). Table 6.10 summarizes the specification details:

Table 6.10 Specification detail for uncertain correlations

The csv_initial_state and dsv_initial_state specifications define the initial values for the continuous and discrete state variables which will be passed through to the simulator (e.g., in order to define parameterized modeling controls). The csv_lower_bounds, csv_upper_bounds, dsv_lower_-
6.6 State Variables

bounds, and dsv\_upper\_bounds restrict the size of the state parameter space and are frequently used to define a region for design of experiments or parameter study investigations. The csv\_descriptor and dsv\_descriptor vectors provide strings which will be replicated through the DAKOTA output to help identify the numerical values for these parameters. Default values for optional specifications are zeros for initial states, positive and negative machine limits for upper and lower bounds (+/- DBL\_MAX, INT\_MAX, INT\_MIN from the float.h and limits.h system header files), and numbered strings for descriptors.
Chapter 7

Interface Commands

7.1 Interface Description

The interface section in a DAKOTA input file specifies how function evaluations will be performed. Function evaluations can be performed using either an interface with a simulation code or an interface with an approximation method.

In the former case of a simulation, the application interface is used to invoke the simulation with either system calls, forks, direct function invocations, or XML socket invocations. In the system call and fork cases, communication between DAKOTA and the simulation occurs through parameter and response files. In the direct function case, communication occurs through the function parameter list. The direct case can involve linked simulation codes or polynomial test functions which are compiled into the DAKOTA executable. The polynomial test functions allow for rapid testing of algorithms without process creation overhead or engineering simulation expense. The XML case is experimental and under development. More information and examples on interfacing with simulations are provided in Application Interface.

In the case of an approximation, an approximation interface can be selected to make use of the global, local, multipoint, and hierarchical surrogate modeling capabilities available within DAKOTA’s Approximation-Interface class and DakotaApproximation class hierarchy (see Approximation Interface).

Several examples follow. The first example shows an application interface specification which specifies the use of system calls, the names of the analysis executable and the parameters and results files, and that parameters and responses files will be tagged and saved. Refer to Application Interface for more information on the use of these options.

```plaintext
interface, 
  application system, 
  analysis_drivers = 'rosenbrock' 
  parameters_file = 'params.in' 
  results_file = 'results.out' 
  file_tag 
  file_save
```

The next example shows a similar specification, except that an external rosenbrock executable has been replaced by use of the internal rosenbrock test function from the DirectFnApplcInterface class.

```plaintext
interface, 
```
The final example shows an approximation interface specification which selects a quadratic polynomial approximation from among the global approximation algorithms. It uses a pointer to a design of experiments method for generating the data needed for building a global approximation, reuses any old data available for the current approximation region, and employs the scaled approach to correcting the approximation at the center of the current approximation region.

```plaintext
interface, approximation global, polynomial
dace_method_pointer = 'DACE'
reuse_samples region
correction scaled
```

### 7.2 Interface Specification

The interface specification has the following top-level structure:

```plaintext
interface,
    <set identifier>
    <application specification> or
    <approximation specification>
```

where the application specification can be broken down into

```plaintext
interface,
    <set identifier>
    application
        <system call specification> or
        <fork specification> or
        <direct function specification> or
        <xml specification>
```

and the approximation specification can be broken down into

```plaintext
interface,
    <set identifier>
    approximation
        <global specification> or
        <multipoint specification> or
        <local specification> or
        <hierarchical specification>
```

Referring to `dakota.input.spec`, it is evident from the brackets that the set identifier is an optional specification, and from the required groups (enclosing in parentheses) separated by OR’s, that either an application or approximation interface must be specified. The optional set identifier can be used to provide a unique identifier string for labeling a particular interface specification. A method can then identify the use of a particular interface by specifying this label in its `interface_pointer` specification. If an application interface is specified, its type must be system, fork, direct, or xml. If an approximation interface is specified, its type must be global, multipoint, local, or hierarchical. The following sections describe each of these interface specification components in additional detail.
7.3 Interface Set Identifier

The optional set identifier specification uses the keyword \texttt{id\_interface} to input a string for use in identifying a particular interface specification with a particular method (see also \texttt{interface\_pointer} in Method Independent Controls). For example, a method whose specification contains \texttt{interface\_pointer = 'I1'} will use an interface specification with \texttt{id\_interface = 'I1'}.

It is appropriate to omit an \texttt{id\_interface} string in the interface specification and a corresponding \texttt{interface\_pointer} string in the method specification if only one interface specification is included in the input file, since the binding of a method to an interface is unambiguous in this case. More specifically, if a method omits specifying an \texttt{interface\_pointer}, then it will use the last interface specification parsed, which has the least potential for confusion when only a single interface specification exists. Table 7.1 summarizes the set identifier inputs.

Table 7.1 Specification detail for set identifier

<table>
<thead>
<tr>
<th>Description</th>
<th>Keyword</th>
<th>Associated Data</th>
<th>Status</th>
<th>Default</th>
</tr>
</thead>
<tbody>
<tr>
<td>Interface set identifier</td>
<td>id_interface</td>
<td>string</td>
<td>Optional</td>
<td>use of last interface parsed</td>
</tr>
</tbody>
</table>

7.4 Application Interface

The application interface uses a simulator program, and optionally filter programs, to perform the parameter to response mapping. The simulator and filter programs are invoked with system calls, forks, XML, or direct function calls. In the system call and fork cases, files are used for transfer of parameter and response data between DAKOTA and the simulator program. This approach is simple and reliable and does not require any modification to simulator programs. In the XML case, packets of parameter and response data are passed over sockets for enabling distribution of simulation resources. This capability utilizes the IDEA framework and is experimental and incomplete. In the direct function case, the function parameter list is used to pass the parameter and response data. This approach requires modification to simulator programs so that they can be linked into DAKOTA; however it can be more efficient through the elimination of process creation overhead, can be less prone to loss of precision in that data can be passed directly rather than written to and read from a file, and can enable completely internal management of multiple levels of parallelism through the use of MPI communicator partitioning.

The application interface group specification contains several specifications which are valid for all application interfaces as well as additional specifications pertaining specifically to system call, fork, xml, or direct application interfaces. Table 7.2 summarizes the specifications valid for all application interfaces, and Tables 7.3, 7.4, 7.5, and 7.6 summarize the additional specifications for system call, fork, xml, and direct function application interfaces, respectively.

In Table 7.2, the required \texttt{analysis\_drivers} specification provides the names of executable analysis programs or scripts which comprise a function evaluation. The common case of a single analysis driver is simply accommodated by specifying a list of one driver (this also provides backward compatibility with previous DAKOTA versions). The optional \texttt{input\_filter} and \texttt{output\_filter} specifications provide the names of separate pre- and post-processing programs or scripts which assist in mapping DAKOTA parameters files into analysis input files and mapping analysis output files into DAKOTA results files, respectively. If there is only a single analysis driver, then it is usually most convenient to combine pre- and post-processing requirements into a single analysis driver script and omit the separate input and output filters. However, in the case of multiple analysis drivers, the input and output filters provide a convenient location for non-repeated pre- and post-processing requirements. That is, input and output filters are only executed once per function evaluation, regardless of the number of analysis drivers, which makes them convenient locations for data processing operations which only need to be performed once per function.
evaluation.

The optional asynchronous flag specifies use of asynchronous protocols (i.e., background system calls, nonblocking forks, POSIX threads) when evaluations or analyses are invoked. The evaluation_concurrency and analysis_concurrency specifications serve a dual purpose:

- when running DAKOTA on a single processor in asynchronous mode, the default concurrency of evaluations and analyses is all concurrency that is available. The evaluation_concurrency and analysis_concurrency specifications can be used to limit this concurrency in order to avoid machine overload or usage policy violation.
- when running DAKOTA on multiple processors in message passing mode, the default concurrency of evaluations and analyses on each of the servers is one (i.e., the parallelism is exclusively that of the message passing). With the evaluation_concurrency and analysis_concurrency specifications, a hybrid parallelism can be selected through combination of message passing parallelism with asynchronous parallelism on each server.

The optional evaluation_servers and analysis_servers specifications support user overrides of the automatic parallel configuration (refer to ParallelLibrary) for the number of evaluation servers and the number of analysis servers. Similarly, the optional evaluation_self_scheduling, evaluation_static_scheduling, analysis_self_scheduling, and analysis_static_scheduling specifications can be used to override the automatic parallel configuration of scheduling approach at the evaluation and analysis parallelism levels. That is, if the automatic configuration is undesirable for some reason, the user can enforce a desired number of partitions and a desired scheduling policy at these parallelism levels.

Failure capturing in application interfaces is governed by the failure_capture specification. Supported directives for mitigating captured failures are abort (the default), retry, recover, and continuation. The retry selection supports an integer input for specifying a limit on retries, and the recover selection supports a list of reals for specifying the dummy function values to use for the failed function evaluation.

The active set vector (ASV) usage setting allows the user to turn off any variability in ASV values so that active set logic can be omitted in the user's simulation interface. This option trades some efficiency for simplicity in interface development. The variable setting results in the default behavior where the ASV values may vary from one function evaluation to the next. Since the user's interface must return the data set specified in the ASV values, this interface must contain additional logic to account for changing ASV values. Setting the ASV control to constant causes DAKOTA to always request a "full" data set (the full function, gradient, and Hessian data that is available from the interface as specified in the responses specification) on each function evaluation. For example, if active_set_vector is specified to be constant and the responses section specifies four response functions, analytic gradients, and no Hessians, then the ASV on every function evaluation will be \{3 3 3 3\}, regardless of what subset of this data is currently needed. While wasteful of computations in many instances, this removes the need for ASV-related logic in user interfaces since it allows the user to return the same data set on every evaluation. Conversely, if active_set_vector is specified to be variable (or the specification is omitted resulting in default behavior), then the ASV requests in this example might vary from \{1 1 1 1\} to \{2 0 0 2\}, etc., according to the specific data needed on a particular function evaluation. This will require the user's interface to read the ASV requests and perform the appropriate logic in conditionally returning only the data requested. In general, the default variable behavior is recommended for efficiency through the elimination of unnecessary computations, although in some instances, ASV control set to constant can simplify operations and speed filter development for time critical applications. Note that in all cases, the data returned to DAKOTA from the user's interface must match the ASV passed in (or else a response recovery error will result). However, when the ASV values are held constant, they need not be checked on every evaluation. Note: Setting the ASV control to constant can have a positive effect on load balancing for parallel DAKOTA executions. Thus, there is significant overlap in this ASV control option with speculative gradients (see Method Independent Controls). There is also overlap with the mode override approach used with
certain optimizers (see **SNLLOptimizer**) to combine individual value, gradient, and Hessian requests.

In addition to the general application interface specifications, the type of application interface involves a selection between **system**, **fork**, **xml**, or **direct** required group specifications. The following sections describe these group specifications in detail.
7.4.1 System call application interface

For system call interfaces, the parameters file, results file, analysis usage, aprepro, file_tag, and file_save are additional settings within the group specifications. The parameters and results file names are supplied as strings using the parameters file and results file specifications. Both specifications are optional with the default data transfer files being Unix temporary files (e.g., /usr/tmp/aaaa08861). The parameters and results file names are passed on the command line of the system calls or as arguments in the execvp() function of the fork application interface. Special analysis command syntax can be entered as a string with the analysis usage specification. This special syntax replaces the normal system call combination of the specified analysis drivers with command line arguments; however, it does not affect the input_filter and output_filter syntax (if filters are present). Note that if there are multiple analysis drivers, then analysis usage must include the syntax for all analyses in a single string (typically separated by semi-colons). The default is no special syntax, such that the analysis drivers will be used in the standard way as described in the Users Manual. The format of data in the parameters files can be modified for direct usage with the APREPRO pre-processing tool using the aprepro specification. File tagging (appending parameters and results files with the function evaluation number) and file saving (leaving parameters and results files in existence after their use is complete) are controlled with the file_tag and file_save flags. If these specifications are omitted, the default is no file tagging (no appended function evaluation number) and no file saving (files will be removed after a function evaluation). File tagging is most useful when multiple function evaluations are running simultaneously using files in a shared disk space, and file saving is most useful when debugging the data communication between DAKOTA and the simulation. The additional specifications for system call application interfaces are summarized in Table 7.3.

7.4.2 Fork application interface

For fork application interfaces, the parameters file, results file, aprepro, file_tag, and file_save are additional settings within the group specification and have identical meanings to those for the system call application interface. The only difference in specifications is that fork interfaces do not support an analysis usage specification due to limitations in the execvp() function used when forking a process. The additional specifications for fork application interfaces are summarized in Table 7.4.

#### 7.4.3 XML application interface

For XML application interfaces, hostnames and processors_per_host are additional settings within the required group. hostnames provides a list of machines for use in distributing evaluations, and processors_per_host specified the number of processors to use from each host. This capability is a placeholder for future work with the IDEA framework and is not currently operational. The additional specifications for XML application interfaces are summarized in Table 7.5.

#### 7.4.4 Direct function application interface

For direct function application interfaces, processors_per_analysis is an additional setting within the required group which is used to configure multiprocessor analysis partitions. As with the evaluation_servers, analysis_servers, evaluation_self_scheduling, evaluation_static_scheduling, analysis_self_scheduling, and analysis_static_scheduling specifications described above in Application Interface, processors_per_analysis provides a means for the user to override the automatic parallel configuration (refer to ParallelLibrary) for the number of processors used for each analysis partition. Note that if both analysis_servers and processors_per_analysis are specified and they are not in agreement, then analysis_servers takes precedence. The direct application interface specifications are summarized in Table 7.6.

</tbody>
</table>
Currently, only the SALINAS structural dynamics code is available as a linked simulation code, although
the SIERRA multiphysics framework is scheduled to be supported in future releases. The more common
usage of the direct interface is the use of internal test problems which are available for performing pa-
rameter to response mappings as inexpensively as possible. These problems are compiled directly into
the DAKOTA executable as part of the direct function application interface class and are used for algorithm
testing. Refer to DirectFnApplicInterface for currently available testers.

7.5 Approximation Interface

The approximation interface uses an approximate representation of a "truth" model to perform the param-
eter to response mapping. This approximation, or surrogate model, is built and updated using data from
the truth model. This data is generated in some cases using a design of experiments iterator applied to the
truth model (global approximations with a dace_method_pointer). In other cases, truth model data
from a single point (local, hierarchical approximations), from a few previously evaluated points (multi-
point approximations), or from the restart database (global approximations with reuse_samples) can
be used. Approximation interfaces are used extensively in the surrogate-based optimization strategy (see
SurrBasedOptStrategy and Surrogate-based Optimization Commands), in which the goals are to reduce
expense by minimizing the number of truth function evaluations and to smooth out noisy data with a global
data fit. However, the use of approximation interfaces is not restricted in any way to optimization tech-
niques, and in fact, the uncertainty quantification methods and optimization under uncertainty strategy are
other primary users.

The approximation interface specification requires the specification of one of the following approximation
types: global, multipoint, local, or hierarchical. Each of these specifications is a required
group with several additional specifications. The following sections present each of these specification
groups in further detail.

7.5.1 Global approximation interface

The global approximation interface specification requires the specification of one of the following approx-
imation methods: neural_network, polynomial, mars, hermite, or kriging. These specifications
invoke a layered perceptron artificial neural network approximation, a quadratic polynomial regres-
sion approximation, a multivariate adaptive regression spline approximation, a hermite polynomial approx-
imation, or a kriging interpolation approximation, respectively. In the kriging case, a vector of correlations
can be optionally specified in order to bypass the internal kriging calculations of correlation coefficients.
For each of the global approximation methods, dace_method_pointer, reuse_samples, correction,
and use_gradients can be optionally specified. The dace_method_pointer specification
points to a design of experiments iterator which can be used to generate truth model data for building a
global data fit. The reuse_samples specification can be used to employ old data (either from previ-
ous function evaluations performed in the run or from function evaluations read from the restart database)
in the building of new global approximations. The default is no reuse of old data (since this can induce
bias), and the settings of all and region result in reuse of all available data and all data available in the current trust region, respectively. The combination of new build data from dace\_{method\_pointer} and old build data from reuse\_{samples} must be sufficient for building the global approximation. If not enough data is available, the system will abort with an error message. Both dace\_{method\_pointer} and reuse\_{samples} are optional specifications, which gives the user maximum flexibility in using design of experiments data, restart data, or both. The \textbackslash correction specification specifies that a correction technique will be applied to the approximation in order for the approximation to match truth data (value or both value and gradient) at a particular point (e.g., the center of the approximation region). Available techniques include offset for adding a +/- offset to the approximation to match a truth value at a point, scaled for multiplying the approximation by a scalar to match a truth value at a point, and \textbackslash beta for multiplying the approximation by a function to match the truth value and the truth gradient at a point. Finally, the use\_gradients flag specifies a future capability for the use of gradient data in the global approximation builds. This capability is currently supported in SurrBasedOptStrategy, SurrogateDataPoint, and DakotaApproximation::build(), but is not yet supported in any global approximation derived class redefinitions of DakotaApproximation::find\_coefficients(). Table 7.7 summarizes the global approximation interface specifications.

7.5.2 Multipoint approximation interface

Multipoint approximations use data from previous design points to improve the accuracy of local approximations. This specification is a placeholder for future capability as no multipoint approximation algorithms are currently available. Table 7.8 summarizes the multipoint approximation interface specifications.

7.5.3 Local approximation interface

Local approximations use value and gradient data from a single point to form a series expansion for approximating data in the vicinity of this point. The currently available local approximation is the taylor-series selection. This is a first order Taylor series expansion, also known as the "linear approximation" in the optimization literature. Other local approximations, such as the "reciprocal" and "conservative/convex" approximations, may become available in the future. The required actual_interface_pointer specification and the optional actual_interface_responses_pointer specification are the additional inputs for local approximations. The former points to an interface specification which provides the truth model for generating the value and gradient data used in the series expansion. And the latter can be used to employ a different responses specification for the truth model than that used for mappings from the local approximation. For example, the truth model may generate gradient data using finite differences (as specified in the responses specification identified by actual_interface_responses_pointer), whereas the local approximation may return (approximate) analytic gradients (as specified in a different responses specification which is identified by the method using the local approximation as its interface). If actual_interface_responses_pointer is not specified, then the response set available from truth model evaluations and approximation interface mappings will be the same. Table 7.9 summarizes the local approximation interface specifications.

7.5.4 Hierarchical approximation interface

Hierarchical approximations use corrected results from a low fidelity interface as an approximation to the results of a high fidelity "truth" model. The required low_fidelity_interface_pointer specification points to the low fidelity interface specification. This interface is used to generate low fidelity responses which are then corrected and returned to an iterator. The required high_fidelity_interface_pointer specification points to the interface specification for the high fidelity truth model. This model is used only when new correction factors for the low fidelity interface are needed. The correction specification specifies which correction technique will be applied to the low fidelity results in order to match the high fidelity results (value or both value and gradient) at a particular point (e.g., the center of the approximation region). In the hierarchical case (as compared to the global case), the correction specification is required, since the omission of a correction technique would effectively waste all high fidelity evaluations. If it is desired to use a low fidelity model without corrections, then a hierarchical approximation is not needed and a single application interface should be used. Available correction techniques are offset, scaled, and beta, as described previously in Global approximation interface. Table 7.10 summarizes the hierarchical approximation interface specifications.

Chapter 8

Responses Commands

8.1 Responses Description

The responses specification in a DAKOTA input file specifies the data set that can be recovered from the interface after the completion of a "function evaluation." Here, the term function evaluation is used somewhat loosely to denote a data request from an iterator that is mapped through an interface in a single pass. Strictly speaking, this data request may actually involve multiple response functions and their derivatives, but the term function evaluation is widely used for this purpose. The data set is made up of a set of functions, their first derivative vectors (gradients), and their second derivative matrices (Hessians). This abstraction provides a generic data container (the DakotaResponse class) whose contents are interpreted differently depending upon the type of iteration being performed. In the case of optimization, the set of functions consists of one or more objective functions, nonlinear inequality constraints, and nonlinear equality constraints. Linear constraints are not part of a response set since their coefficients can be communicated to an optimizer at start up and then computed internally for all function evaluations (see Method Independent Controls). In the case of least squares iterators, the functions consist of individual residual terms (as opposed to a sum of the squares objective function). In the case of nondeterministic iterators, the function set is made up of generic response functions for which the effect of parameter uncertainty is to be quantified. Lastly, parameter study iterators may be used with any of the response data set types. Within the C++ implementation, the same data structures are used to provide each of these response data set types; only the interpretation of the data varies from iterator branch to iterator branch.

Gradient availability may be described by \texttt{no\_gradients}, \texttt{numerical\_gradients}, \texttt{analytic\_gradients}, or \texttt{mixed\_gradients}. \texttt{no\_gradients} means that gradient information is not needed in the study. \texttt{numerical\_gradients} means that gradient information is needed and will be computed with finite differences using either the native or one of the vendor finite differencing routines. \texttt{analytic\_gradients} means that gradient information is available directly from the simulation (finite differencing is not required). And \texttt{mixed\_gradients} means that some gradient information is available directly from the simulation whereas the rest will have to be finite differenced.

Hessian availability may be described by \texttt{no\_hessians} or \texttt{analytic\_hessians} where the meanings are the same as for the corresponding gradient availability settings. Numerical Hessians are not currently supported, since, in the case of optimization, this would imply a finite difference-Newton technique for which a direct algorithm already exists. Capability for numerical Hessians can be added in the future if the need arises.

The responses specification provides a description of the total data set that is available for use by the iterator
during the course of its iteration. This should be distinguished from the data subset described in an active set vector (see DAKOTA File Data Formats in the Users Manual) which describes the particular subset of the response data needed for an individual function evaluation. In other words, the responses specification is a broad description of the data that is available whereas the active set vector describes the particular subset of the available data that is currently needed.

Several examples follow. The first example shows an optimization data set containing an objective function and two nonlinear inequality constraints. These three functions have analytic gradient availability and no Hessian availability.

```
responses, 
  num_objective_functions = 1 
  num_nonlinear_inequality_constraints = 2 
  analytic_gradients 
  no_hessians
```

The next example shows a specification for a least squares data set. The six residual functions will have numerical gradients computed using the dakota finite differencing routine with central differences of 0.1% (plus/minus delta value = .001*value).

```
responses, 
  num_least_squares_terms = 6 
  numerical_gradients 
  method_source dakota 
  interval_type central 
  fd_step_size = .001 
  no_hessians
```

The last example shows a specification that could be used with a nondeterministic iterator. The three response functions have no gradient or Hessian availability; therefore, only function values will be used by the iterator.

```
responses, 
  num_response_functions = 3 
  no_gradients 
  no_hessians
```

Parameter study iterators are not restricted in terms of the response data sets which may be catalogued; they may be used with any of the function specification examples shown above.

### 8.2 Responses Specification

The responses specification has the following structure:

```
responses, 
  <set identifier> 
  <function specification> 
  <gradient specification> 
  <Hessian specification>
```

Referring to `dakota.input.spec`, it is evident from the enclosing brackets that the set identifier is optional. However, the function, gradient, and Hessian specifications are all required specifications, each of which contains several possible specifications separated by logical OR’s. The function specification must be one of three types:
The gradient specification must be one of four types:

- no gradients
- numerical gradients
- analytic gradients
- mixed gradients

And the Hessian specification must be one of two types:

- no Hessians
- analytic Hessians

The optional set identifier can be used to provide a unique identifier string for labeling a particular responses specification. A method can then identify the use of a particular response set by specifying this label in its responses_pointer specification. The function, gradient, and Hessian specifications define the data set that can be recovered from the interface. The following sections describe each of these specification components in additional detail.

### 8.3 Responses Set Identifier

The optional set identifier specification uses the keyword `id_responses` to input a string for use in identifying a particular responses set with a particular method (see also responses_pointer in the Method Independent Controls). For example, a method whose specification contains `responses_pointer = 'R1'` will use a responses set with `id_responses = 'R1'`.

If this specification is omitted, a particular responses specification will be used by a method only if that method omits specifying a responses_pointer and if the responses set was the last set parsed (or is the only set parsed). In common practice, if only one responses set exists, then `id_responses` can be safely omitted from the responses specification and responses_pointer can be omitted from the method specification(s), since there is no potential for ambiguity in this case. **Table 8.1** summarizes the set identifier inputs.

**Table 8.1 Specification detail for set identifier**

### 8.4 Function Specification

The function specification must be one of three types: 1) a group containing objective and constraint functions, 2) a least squares terms specification, or 3) a response functions specification. These function sets correspond to optimization, least squares, and uncertainty quantification iterators, respectively. Parameter study and design of experiments iterators may be used with any of the three function specifications.
8.4.1 Objective and constraint functions (optimization data set)

An optimization data set is specified using `num_objective_functions` and optionally `multi_objective_weights`, `num_nonlinear_inequality_constraints`, `num_nonlinear_inequality_lower_bounds`, `num_nonlinear_inequality_upper_bounds`, `num_nonlinear_equality_constraints`, and `num_nonlinear_equality_targets`. `num_objective_functions`, `num_nonlinear_inequality_constraints`, and `num_nonlinear_equality_constraints` specify the number of objective functions, nonlinear inequality constraints, and nonlinear equality constraints, respectively. The number of objective functions must be 1 or greater, and the number of inequality and equality constraints must be 0 or greater. If the number of objective functions is greater than 1, then a `multi_objective_weights` specification provides a simple weighted-sum approach to combining multiple objectives:

\[
  f = \sum_{i=1}^{n} w_i f_i
\]

If this is not specified, then each objective function is given equal weighting:

\[
  f = \sum_{i=1}^{n} \frac{f_i}{n}
\]

`nonlinear_inequality_lower_bounds` and `nonlinear_inequality_upper_bounds` specifications provide the lower and upper bounds for 2-sided nonlinear inequalities of the form

\[
  g_l \leq g(x) \leq g_u
\]

The defaults for the inequality constraint bounds are selected so that one-sided inequalities of the form

\[
  g(x) \leq 0.0
\]

result when there are no user constraint bounds specifications (this provides backwards compatibility with previous DAKOTA versions). In a user bounds specification, any upper bound values greater than +bigBoundSize (1.e+30, as defined in `DakotaOptimizer`) are treated as +infinity and any lower bound values less than -bigBoundSize are treated as -infinity. This feature is commonly used to drop one of the bounds in order to specify a 1-sided constraint (just as the default lower bounds drop out since -DBL_MAX < -bigBoundSize). The same approach is used for the linear inequality bounds as described in `Method Independent Controls`.

The `nonlinear_equality_targets` specification provides the targets for nonlinear equalities of the form

\[
  g(x) = g_t
\]

and the defaults for the equality targets enforce a value of 0.0 for each constraint

\[
  g(x) = 0.0
\]

Any linear constraints present in an application need only be input to an optimizer at start up and do not need to be part of the data returned on every function evaluation (see the linear constraints description in `Method Independent Controls`). Table 8.2 summarizes the optimization data set specification.

### 8.4.2 Least squares terms (least squares data set)

A least squares data set is specified using num\_least\_squares\_terms. Each of these terms is a residual function to be driven toward zero. These types of problems are commonly encountered in parameter estimation and model validation. Least squares problems are most efficiently solved using special-purpose least squares solvers such as Gauss-Newton or Levenberg-Marquardt; however, they may also be solved using general-purpose optimization algorithms. It is important to realize that, while DAKOTA can solve these problems with either least squares or optimization algorithms, the response data sets to be returned from the simulator are different. Least squares involves a set of residual functions whereas optimization involves a single objective function (sum of the squares of the residuals), i.e.

\[ f = \sum_{i=1}^{n}(R_i)^2 \]

where \( f \) is the objective function and the set of \( R_i \) are the residual functions. Therefore, derivative data in the least squares case involves derivatives of the residual functions, whereas the optimization case involves derivatives of the sum of the squares objective function. Switching between the two approaches will likely require different simulation interfaces capable of returning the different granularity of response data required. Table 8.3 summarizes the least squares data set specification.

8.4.3 Response functions (generic data set)

A generic response data set is specified using `num_response_functions`. Each of these functions is simply a response quantity of interest with no special interpretation taken by the method in use. This type of data set is used by uncertainty quantification methods, in which the effect of parameter uncertainty on response functions is quantified, and can also be used in parameter study and design of experiments methods (although these methods are not restricted to this data set), in which the effect of parameter variations on response functions is evaluated. Whereas objective, constraint, and residual functions have special meanings for optimization and least squares algorithms, the generic response function data set need not have a specific interpretation and the user is free to define whatever functional form is convenient. Table 8.4 summarizes the generic response function data set specification.

8.5 Gradient Specification

The gradient specification must be one of four types: 1) no gradients, 2) numerical gradients, 3) analytic gradients, or 4) mixed gradients.

8.5.1 No gradients

The `no_gradients` specification means that gradient information is not needed in the study. Therefore, it will neither be retrieved from the simulation nor computed with finite differences. `no_gradients` is a complete specification for this case.

8.5.2 Numerical gradients

The `numerical_gradients` specification means that gradient information is needed and will be computed with finite differences using either the native or one of the vendor finite differencing routines.

The `method_source` setting specifies the source of the finite differencing routine that will be used to compute the numerical gradients: `dakota` denotes DAKOTA's internal finite differencing algorithm and `vendor` denotes the finite differencing algorithm supplied by the iterator package in use (DOT, NPSOL, and OPT++ each have their own internal finite differencing routines). The `dakota` routine is the default since it can execute in parallel and exploit the concurrency in finite difference evaluations (see Exploiting Parallelism in the Users Manual). However, the `vendor` setting can be desirable in some cases since certain libraries will modify their algorithm when the finite differencing is performed internally. Since the selection of the `dakota` routine hides the use of finite differencing from the optimizers (the optimizers are configured to accept user-supplied gradients, which some algorithms assume to be of analytic accuracy), the potential exists for the `vendor` setting to trigger the use of an algorithm more optimized for the higher expense and/or lower accuracy of finite-differencing. For example, NPSOL uses gradients in its line search when in user-supplied gradient mode (since it assumes they are inexpensive), but uses a value-based line search procedure when internally finite differencing. The use of a value-based line search will often reduce...
total expense in serial operations. However, in parallel operations, the use of gradients in the NPSOL line search (user-supplied gradient mode) provides excellent load balancing without need to resort to speculative optimization approaches. In summary, then, the dakota routine is preferred for parallel optimization, and the vendor routine may be preferred for serial optimization in special cases.

The interval_type setting is used to select between forward and central differences in the numerical gradient calculations. The DAKOTA, DOT, and OPT++ routines have both forward and central differences available, and NPSOL starts with forward differences and automatically switches to central differences as the iteration progresses (the user has no control over this).

Lastly, fd_step_size specifies the relative finite difference step size to be used in the computations. For DAKOTA, DOT, and OPT++, the intervals are computed by multiplying the fd_step_size with the current parameter value. In this case, a minimum absolute differencing interval is needed when the current parameter value is close to zero. This prevents finite difference intervals for the parameter which are too small to distinguish differences in the response quantities being computed. DAKOTA, DOT, and OPT++ all use 1.e-2*fd_step_size as their minimum absolute differencing interval. With a fd_step_size = .001, for example, DAKOTA, DOT, and OPT++ will use intervals of .001*current value with a minimum interval of 1.e-5. NPSOL uses a different formula for its finite difference intervals: fd_step_size = e-2*current_value*(1+current parameter value)]. This definition has the advantage of eliminating the need for a minimum absolute differencing interval since the interval no longer goes to zero as the current parameter value goes to zero. Table 8.5 summarizes the numerical gradient specification.

### 8.5.3 Analytic gradients

The analytic_gradients specification means that gradient information is available directly from the simulation (finite differencing is not required). The simulation must return the gradient data in the DAKOTA format (see DAKOTA File Data Formats in the Users Manual) for the case of file transfer of data. analytic_gradients is a complete specification for this case.

### 8.5.4 Mixed gradients

The mixed_gradients specification means that some gradient information is available directly from the simulation (analytic) whereas the rest will have to be finite differenced (numerical). This specification allows the user to make use of as much analytic gradient information as is available and then to finite difference for the rest. For example, the objective function may be a simple analytic function of the design variables (e.g., weight) whereas the constraints are nonlinear implicit functions of complex analyses (e.g., maximum stress). The id_analytic list specifies by number the functions which have analytic gradients, and the id_numerical list specifies by number the functions which must use numerical gradients. The method_source, interval_type, and fd_step_size specifications are as described previ-
mixedly in **Numerical gradients** and pertain to those functions listed by the `id_numerical` list. Table 8.6 summarizes the mixed gradient specification.

### 8.6 Hessian Specification

Hessian availability must be specified with either `no_hessians` or `analytic_hessians`. Numerical Hessians are not currently supported, since, in the case of optimization, this would imply a finite difference-Newton technique for which a direct algorithm already exists. Capability for numerical Hessians can be added in the future if the need arises.

#### 8.6.1 No Hessians

The `no_hessians` specification means that the method does not require Hessian information. Therefore, it will neither be retrieved from the simulation nor computed with finite differences. `no_hessians` is a complete specification for this case.

#### 8.6.2 Analytic Hessians

The `analytic_hessians` specification means that Hessian information is available directly from the simulation. The simulation must return the Hessian data in the DAKOTA format (see DAKOTA File Data Formats in Users Manual) for the case of file transfer of data. `analytic_hessians` is a complete specification for this case.
